

Daml SDK Documentation

Digital Asset

Version : 2.10.1

Table of contents

Table of contents	i
1 Introduction To Multi-Party Applications and Daml	1
1.1 Multi-Party Applications	1
1.2 Why Do Multi-Party Applications Matter?	1
1.3 What Is a Multi-Party Application?	3
1.4 Important Concepts in Multi-Party Applications	3
1.5 Key Architectural Concepts in Daml	4
1.6 Transfer Example Using Daml	6
1.7 Next Steps	6
2 System Requirements	8
2.1 Feature/Component System Requirements	8
3 Install the SDK	9
3.1 Install the Dependencies	9
3.2 Choose Daml Enterprise or Daml Open Source	9
3.3 Install Daml Open Source SDK	10
3.3.1 Windows 10	10
3.3.2 Mac and Linux	10
3.4 Install Daml Enterprise	10
3.5 Download Manually	10
3.6 Next Steps	11
4 Set JAVA_HOME and PATH Variables	12
4.1 Windows	12
4.1.1 Set the JAVA_HOME Variable	12
4.1.2 Set the PATH Variable	12
4.2 Mac OS	12
4.3 Linux	13
4.3.1 Set the JAVA_HOME Variable	13
4.3.2 Set the PATH Variable	14
4.3.3 Verify the Changes	14
5 Manual Installation	15
5.1 Install the SDK from a Tarball	15
5.2 Verify the Integrity of a Tarball	16
6 Getting Started with Daml	19
6.1 Prerequisites	19
6.2 Run the App	20

7	App Architecture	24
7.1	The Daml Model	25
7.2	TypeScript Code Generation	27
7.3	The UI	27
8	Your First Feature	30
8.1	Daml Changes	30
8.2	Messaging UI	31
8.2.1	MessageList Component	32
8.2.2	MessageEdit Component	33
8.2.3	MainView Component	34
8.3	Run the Updated UI	35
8.4	Next Steps	37
9	Test Your App	38
9.1	Set Up the Tests	38
9.2	Example: Log In and Out	39
9.3	Accessing UI Elements	40
9.4	Writing CSS Selectors	41
9.5	The Full Test Suite	42
10	Important Considerations When Building Applications With Daml	51
10.1	Overall Considerations	51
10.2	Developer Considerations	51
10.3	Operational Considerations	52
10.4	Next Steps	53
11	Write Smart Contracts with Daml	54
11.1	An Introduction to Daml	54
11.2	Basic Contracts	54
11.2.1	Daml Ledger Basics	55
11.2.2	Daml Modules and Files	55
11.2.3	Templates	55
11.2.4	Signatories	56
11.2.5	Next Up	56
11.3	Test Templates Using Daml Script	56
11.3.1	Script Basics	56
11.3.2	Run the Scripts	57
11.3.3	Test for Failure	58
11.3.4	Archive Contracts	60
11.3.5	View the Ledger and Ledger History	60
11.3.6	Exercises	62
11.3.7	Next Up	62
11.4	Data Types	62
11.4.1	Native Types	63
11.4.2	Assemble Types	65
11.4.3	Manipulate Data	72
11.4.4	Contract Keys	73
11.4.5	Next Up	76
11.5	Transform Data Using Choices	77
11.5.1	Choices as Methods	77
11.5.2	Choices as Delegation	79

11.5.3	Choices In the Ledger Model	79
11.5.4	A Simple Cash Model	81
11.5.5	Next Up	82
11.6	Add Constraints to a Contract	82
11.6.1	Template Preconditions	83
11.6.2	Assertions	84
11.6.3	Time on Daml Ledgers	86
11.6.4	Actions and <code>do</code> Blocks	87
11.6.5	Failing Actions	89
11.6.6	A Sample Action	90
11.6.7	Errors	91
11.6.8	Next Up	92
11.7	Parties and Authority	92
11.7.1	Preventing IOU Revocation	92
11.7.2	Use Propose-Accept Workflows for One-Off Authorization	94
11.7.3	Use Role Contracts for Ongoing Authorization	96
11.7.4	Daml's Authorization Model	98
11.7.5	Next Up	100
11.8	Composing Choices	100
11.8.1	Daml Projects	101
11.8.2	Project Structure	101
11.8.3	Project Overview	102
11.8.4	Composed Choices and Scripts	102
11.8.5	Daml's Execution Model	106
11.8.6	Observers	107
11.8.7	Privacy	107
11.8.8	Next Up	108
11.9	Daml Interfaces	109
11.9.1	Context	109
11.9.2	Interface Definition	110
11.9.3	Interface Instances	112
11.9.4	Using an Interface	113
11.10	Exception Handling	115
11.10.1	Next Up	119
11.11	Work with Dependencies	119
11.11.1	DAR, DALF, Daml-LF, and the Engine	120
11.11.2	Hashes and Identifiers	120
11.11.3	Dependencies and Data Dependencies	121
11.11.4	Structuring Projects	122
11.11.5	Building Multiple Packages	122
11.11.6	Next Up	122
11.12	Functional Programming 101	122
11.12.1	The Haskell Connection	123
11.12.2	Functions	123
11.12.3	Control Flow	128
11.12.4	Next Up	135
11.13	The Daml Standard Library	135
11.13.1	The Prelude	135
11.13.2	Important Types From the Prelude	136
11.13.3	Typeclasses	137
11.13.4	Important Typeclasses From the Prelude	138

11.13.5	Important Modules in the Standard Library	139
11.13.6	Search the Standard Library	140
11.13.7	Next Up	141
11.14	Good Design Patterns	141
11.14.1	The Propose and Accept Pattern	141
11.14.2	The Multiple Party Agreement Pattern	143
11.14.3	The Delegation Pattern	146
11.14.4	The Authorization Pattern	148
11.14.5	The Locking Pattern	150
11.14.6	Diagram Legends	158
11.15	Test Daml Contracts	158
11.15.1	Daml Test Tooling	160
11.15.2	Debug, Trace, and Stacktraces	160
11.15.3	Diagnose Contention Errors	161
11.15.4	Checking Coverage	164
11.15.5	Checking Coverage of External Dependencies	168
11.15.6	Excluding Choices from the Coverage Report	174
11.15.7	Next Up	176
11.16	Next Steps	176
12	Integrate Daml with Off-Ledger Services	177
12.1	Build Applications	177
12.2	Daml Application Architecture	177
12.2.1	Backend	179
12.2.2	Frontend	179
12.2.3	Authorization	180
12.2.4	Developer Workflow	180
12.3	Parties and Users On a Daml Ledger	183
12.3.1	Parties in SDK 2.0 and Subsequent	183
12.3.2	Party ID Hints and Display Names	183
12.3.3	Authorization and User Management	184
12.3.4	Working with Parties	184
12.4	Access Active Contracts with the HTTP JSON API Service	186
12.4.1	HTTP JSON API Service	186
12.4.2	Daml-LF JSON Encoding	228
12.4.3	Query Language	235
12.4.4	Use JavaScript Client Libraries with Daml	238
12.4.5	JSON API Production Setup	244
12.5	Build Integration with the Ledger API	253
12.5.1	What's in the Ledger API	253
12.5.2	How to Access the Ledger API	254
12.5.3	Daml-LF	254
12.5.4	The Ledger API Services	255
12.5.5	Java Bindings	263
12.5.6	Python Bindings	298
12.5.7	Use the Ledger API With gRPC	299
12.5.8	Ledger API Reference	301
12.5.9	How Daml Types are Translated to Protobuf	395
12.5.10	How Daml Types are Translated to Daml-LF	401
12.5.11	Create Your Own Bindings	406
12.6	Write Off-Ledger Automation Using Daml	408

12.6.1	Overview	408
12.6.2	React to Off-Ledger Events: Daml Script	409
12.6.3	React to On-Ledger Events: Daml Triggers (Deprecated)	417
12.7	Handle Errors	444
12.7.1	Command Deduplication	444
12.8	Authorization	451
12.8.1	Introduction	452
12.8.2	Acquire and Use Access Tokens	452
12.8.3	Access Tokens and Rights	453
12.8.4	Access Token Formats	455
12.9	Explicit Contract Disclosure	458
12.9.1	Contract Read Delegation	458
12.9.2	How do stakeholders disclose contracts to submitters?	462
12.9.3	Attaching a disclosed contract to a command submission	462
12.9.4	Trading the stock with explicit disclosure	462
12.9.5	Safeguards	463
13	Resource Management in Daml Application Design	465
13.1	Managing Latency and Throughput	465
13.1.1	Problem Definition	465
13.2	Avoid Contention Issues	470
13.2.1	Contention in Daml	471
13.2.2	Reduce Contention	472
13.2.3	Example Application with Techniques for Reducing Contention	473
13.3	Managing Active Contract Set (ACS) Size	482
13.3.1	Problem Definition	482
13.3.2	Relational Databases	483
13.3.3	HTTP JSON API Service	484
14	Upgrading and Extending Daml Applications	485
14.1	Extending Daml Applications	485
14.2	Upgrading Daml Applications	486
14.2.1	Daml Upgrade Overview	487
14.2.2	Structure Upgrade Contracts	487
14.2.3	Build and Deploy carbon-1.0.0	489
14.2.4	Create carbon-1.0.0 Certificates	489
14.2.5	Build and Deploy carbon-2.0.0	490
14.2.6	Build and Deploy carbon-upgrade	491
14.2.7	Upgrade Existing Certificates from carbon-1.0.0 to carbon-2.0.0	491
14.2.8	Further Steps	492
14.3	Smart Contract Upgrade	492
14.3.1	Overview	492
14.3.2	The Programming Model by Example	500
14.3.3	Package Selection in the Ledger API	521
14.3.4	Migrating to SCU	523
14.3.5	Best Practices	524
14.3.6	Testing	531
14.3.7	SCU Support in Daml Tooling	535
14.4	Automating the Upgrade Process	539
14.4.1	Structure the Upgrade	539
14.4.2	Implementation of the Daml Script	540
14.4.3	Implementation of the Daml Trigger	540

14.4.4	Deploy and Execute the Upgrade	541
15	Developer Tools	543
15.1	Daml Assistant	543
15.1.1	Command Help	544
15.1.2	Configuration Files	544
15.1.3	Managing SDK Versions	547
15.1.4	Build Daml Projects	548
15.1.5	Run Assistant Commands	556
15.2	Daml Shell (<code>daml-shell</code>)	557
15.2.1	Getting started	557
15.2.2	Configuration	560
15.2.3	Usage	561
15.2.4	Transforming and exporting command output	571
15.2.5	FAQ	574
15.3	Canton Console	575
15.3.1	Introduction	575
15.3.2	Run the Canton Console Against the Sandbox	575
15.3.3	Built-in Documentation	575
15.3.4	Interact With the Sandbox	576
15.4	Deploy to a Generic Daml Ledger	576
15.4.1	Connect via TLS	577
15.4.2	Configure Request Timeouts	577
15.5	Experiment: Daml REPL (Deprecated)	577
15.5.1	Usage	577
15.5.2	What Is in Scope at the Prompt?	579
15.5.3	Using Daml REPL Without a Ledger	579
15.5.4	Connecting via TLS	579
15.5.5	Connection to a Ledger With Authorization	580
15.5.6	Using Daml REPL to Convert to JSON	580
15.6	Write: Daml Studio	580
15.6.1	Install	580
15.6.2	Create Your First Daml File	580
15.6.3	Supported Features	582
15.6.4	Common Script Errors	586
15.6.5	Multi-Package Support	589
15.7	Test: Daml Sandbox	592
15.7.1	Run With Authorization	592
15.7.2	Run With TLS	594
15.7.3	Command-line Reference	594
15.7.4	Metrics	595
15.8	Visualize: Daml Navigator (Deprecated)	604
15.8.1	Navigator Functionality	604
15.8.2	Starting Navigator	605
15.8.3	Logging In	605
15.8.4	Viewing Templates or Contracts	607
15.8.5	Using Navigator	611
15.8.6	Authorizing Navigator	613
15.8.7	Advanced Usage	614
15.9	Measure: Daml Profiler	615
15.9.1	Usage	615

15.9.2	Caveats	617
15.10	Daml Codegen	617
15.10.1	Introduction	617
15.10.2	Run the Daml Codegen	617
16	Daml Finance Documentation	620
16.1	Content	620
16.2	Starting Points	620
16.3	Packages	621
16.3.1	How to Download	621
16.3.2	Current Release	621
17	Overview	624
17.1	Introduction	624
17.1.1	Purpose	624
17.1.2	Design Goals	624
17.1.3	Scope	625
17.1.4	Use Cases	625
17.1.5	Exploring the Library	625
17.1.6	Demo Application	626
17.2	Architecture	626
17.2.1	Interface Layer	626
17.2.2	Implementation Layer	627
17.2.3	Versioning and Compatibility	627
17.3	Building Applications	628
17.3.1	Installing Daml Finance	628
17.3.2	Application Architecture	628
17.3.3	Using Daml Codegen	630
17.4	Extending Daml Finance	630
17.4.1	Custom Holding Implementations	631
17.4.2	Custom Account Implementations	631
17.4.3	Custom Instrument Implementations	631
17.4.4	Custom Lifecycle Implementations	632
17.4.5	Custom Settlement Implementations	632
18	Concepts	633
18.1	Asset Model	633
18.1.1	Instrument	633
18.1.2	Holding	634
18.1.3	Account	635
18.1.4	Example setups	637
18.2	Settlement	639
18.2.1	Workflow	639
18.2.2	The components in detail	642
18.2.3	Remarks and further references	645
18.3	Lifecycling	645
18.3.1	Approach	646
18.3.2	Workflow	647
18.3.3	Components	650
18.3.4	Remarks and further references	651
19	Instruments	652

19.1	Bonds	652
19.2	Equites	652
19.3	Options	652
19.4	Structured Products	653
19.5	Swaps	653
19.6	Other Instruments	653
19.7	Token Instrument	653
19.7.1	How to create a Token Instrument	653
19.7.2	How to lifecycle a Token Instrument	654
19.7.3	Frequently Asked Questions	654
19.8	Bond Instrument	654
19.8.1	How to use a Bond Instrument in your application	654
19.8.2	How to Create a Bond Instrument	655
19.8.3	Frequently Asked Questions	662
19.9	Equity Instrument	662
19.9.1	How to use an Equity Instrument in your application	663
19.9.2	The Equity Interface	663
19.9.3	Dividend	663
19.9.4	Bonus issue	664
19.9.5	Dividend option	665
19.9.6	Rights Issue	666
19.9.7	Rights Subscription	667
19.9.8	Stock split	667
19.9.9	Merger	668
19.9.10	Frequently Asked Questions	669
19.10	Option Instrument	670
19.10.1	How To Create an Option Instrument	670
19.10.2	Frequently Asked Questions	674
19.11	Structured Product	675
19.11.1	How to create a Structured Product Instrument	675
19.11.2	Frequently Asked Questions	678
19.12	Swap Instrument	679
19.12.1	Prerequisites	679
19.12.2	How To Create a Swap Instrument	679
19.12.3	Frequently Asked Questions	690
19.13	Generic Instrument	690
19.13.1	How to create a Generic Instrument	690
19.13.2	How to lifecycle a Generic Instrument	691
19.13.3	Frequently Asked Questions	693
19.13.4	Contingent Claims	693

20	Packages	702
20.1	Interface Packages	702
20.1.1	Daml.Finance.Interface.Holding.V4	702
20.1.2	Daml.Finance.Interface.Account.V4	704
20.1.3	Daml.Finance.Interface.Settlement.V4	705
20.1.4	Daml.Finance.Interface.Lifecycle.V4	706
20.1.5	Daml.Finance.Interface.Instrument.Base.V4	708
20.1.6	Daml.Finance.Interface.Claims.V4	709
20.1.7	Daml.Finance.Interface.Data.V4	709
20.1.8	Daml.Finance.Interface.Types.Common.V3	710

20.1.9	Daml.Finance.Interface.Types.Date.V3	711
20.1.10	Daml.Finance.Interface.Util.V3	712
20.1.11	ContingentClaims.Core.V3	713
20.1.12	Daml.Finance.Interface.Instrument.Bond.V3	714
20.1.13	Daml.Finance.Interface.Instrument.Equity.V0	715
20.1.14	Daml.Finance.Interface.Instrument.Generic.V4	716
20.1.15	Daml.Finance.Interface.Instrument.Option.V0	717
20.1.16	Daml.Finance.Interface.Instrument.StructuredProduct.V0	718
20.1.17	Daml.Finance.Interface.Instrument.Swap.V0	719
20.1.18	Daml.Finance.Interface.Instrument.Token.V4	720
20.1.19	Daml.Finance.Interface.Instrument.Types.V2	721
20.2	Implementation Packages	722
20.2.1	Daml.Finance.Holding.V4	722
20.2.2	Daml.Finance.Account.V4	723
20.2.3	Daml.Finance.Settlement.V4	724
20.2.4	Daml.Finance.Lifecycle.V4	726
20.2.5	Daml.Finance.Data.V4	727
20.2.6	Daml.Finance.Claims.V3	728
20.2.7	Daml.Finance.Util.V4	729
20.2.8	ContingentClaims.Lifecycle.V3	730
20.2.9	ContingentClaims.Valuation.V0	731
20.2.10	Daml.Finance.Instrument.Bond.V3	732
20.2.11	Daml.Finance.Instrument.Equity.V0	733
20.2.12	Daml.Finance.Instrument.Generic.V4	734
20.2.13	Daml.Finance.Instrument.Option.V0	735
20.2.14	Daml.Finance.Instrument.StructuredProduct.V0	736
20.2.15	Daml.Finance.Instrument.Swap.V0	737
20.2.16	Daml.Finance.Instrument.Token.V4	738

21	Tutorials	740
21.1	Getting Started	740
21.1.1	Prerequisites	740
21.1.2	Download the Code for the Tutorials	741
21.1.3	Structure of the Code and Dependencies	741
21.1.4	Holdings	741
21.1.5	Transfer	745
21.1.6	Settlement	747
21.1.7	Lifecycling	751
21.2	Settlement	756
21.2.1	Download the Code for the Tutorials	756
21.2.2	Enhanced Transfers	757
21.2.3	Internal Settlement	760
21.2.4	Intermediated Settlement	765
21.3	Lifecycling	770
21.3.1	Download the Code for the Tutorials	770
21.3.2	Time-based lifecycling (using a fixed rate bond)	771
21.3.3	Observations (using a floating rate bond)	776
21.3.4	Election-based lifecycling (using a callable bond)	779
21.4	Upgrade	783
21.4.1	Download the Code for the Tutorials	784
21.4.2	Account Upgrade	785

21.4.3	Holding Upgrade	787
21.5	Payoff Modeling	788
21.5.1	Download the Code for the Tutorials	789
21.5.2	Basic Builders	789
21.5.3	Observations	792
21.6	Advanced Topics	794
21.6.1	Intermediated Lifecycling of an Instrument	795
21.6.2	Leverage Contingent Claims in Custom Instrument Implementations	800
21.6.3	Date Utility Functions: Calendar, Schedule, and Day Count	806

22	Reference	813
22.1	Glossary	813
22.1.1	Account	813
22.1.2	Instrument	813
22.1.3	Holding	814
22.1.4	Fungibility	814
22.1.5	Transferability	814
22.1.6	Locking	814
22.1.7	Crediting / Debiting	814
22.1.8	Disclosure	814
22.1.9	Settlement	814
22.1.10	Lifecycling	815
22.1.11	Lifecycling effect	815
22.2	Patterns	815
22.2.1	Factory pattern	815
22.2.2	Reference pattern	816
22.2.3	View of an interface contract and the <i>GetView</i> choice	816
22.3	Daml Finance	817
22.3.1	ContingentClaims.Core.V3.Builders	817
22.3.2	ContingentClaims.Core.V3.Claim	818
22.3.3	ContingentClaims.Core.V3.Internal.Claim	819
22.3.4	ContingentClaims.Core.V3.Observation	821
22.3.5	ContingentClaims.Core.V3.Util.Recursion	823
22.3.6	ContingentClaims.Lifecycle.V3.Lifecycle	824

23 Canton	1047
23.1 Introduction to Canton	1047
23.2 Overview and Assumptions	1047
23.2.1 Canton 101	1049
23.2.2 Synchronization Domain Entities	1058
23.2.3 Participant-Internal Canton Components	1059
23.2.4 Trust Assumptions	1061
23.3 Canton Demo	1062
23.4 Getting Started	1063
23.4.1 Installation	1063
23.4.2 Starting Canton	1064
23.4.3 The Example Topology	1065
23.4.4 Connecting The Participant Nodes and Synchronization Domains	1067
23.4.5 Canton Identities and Provisioning Parties	1070
23.4.6 Creating Parties	1071
23.4.7 Extracting Identifiers	1072
23.4.8 Provisioning Smart Contract Code	1073
23.4.9 Executing Smart Contracts	1074

23.4.10 Privacy	1079
23.4.11 Your Development Choices	1082
23.4.12 Automation Using Bootstrap Scripts	1082
23.4.13 What Next?	1083
23.5 Daml SDK and Canton	1083
23.5.1 Starting Canton	1084
23.5.2 Running the Create Daml App Example	1085
23.5.3 What Next?	1086
23.6 Composability	1086
23.6.1 Part 1: A multi-synchronization-domain workflow	1087
23.6.2 Part 2: Composing existing workflows	1096
23.7 Versioning	1103
23.7.1 Canton release version	1103
23.7.2 For application developers and operators	1104
23.7.3 For Canton participant and synchronization domain operators	1104

24 Download and Install Canton	1107
24.1 Choosing Open-Source or Enterprise Edition	1107
24.2 Downloading the Open Source Edition	1108
24.3 Downloading the Enterprise Edition	1108
24.4 Install Canton	1108
24.4.1 Hardware Resources	1108
24.4.2 Downloading Canton	1109
24.4.3 Your Topology	1109
24.4.4 The Config Directory Contents	1110
24.4.5 Selecting your Storage Layer	1111
24.4.6 Generate the TLS Certificates	1112
24.4.7 Setting up a Participant	1113
24.4.8 Setting up a Synchronization Domain	1114
24.4.9 Multi-Node Setup	1115
24.5 Work With the Docker Containers	1116
24.5.1 Obtaining the Docker Images	1116
24.5.2 Starting Canton	1116
24.5.3 Configuring Logging and Health Probes	1116
24.5.4 Administrating the Running Node	1117
24.5.5 Exposing the Ledger API or Admin API to the host machine	1117
24.5.6 Supplying custom configuration and DARs	1117
24.5.7 Running Postgres in Docker	1117
24.6 Set Configuration Options	1118
24.6.1 Configuration reference	1119
24.6.2 Configuration Compatibility	1119
24.6.3 Advanced Configurations	1119
24.6.4 Configuration Mixin	1120
24.6.5 Multiple Synchronization Domains	1121
24.6.6 Fail Fast Mode	1122
24.6.7 Init Configuration	1122
24.7 Set Up A Daml Domain With Enterprise Drivers	1123
24.7.1 Oracle Synchronization Domain	1123
24.7.2 Fabric Synchronization Domain	1123
24.7.3 Ethereum Synchronization Domain	1128

25 High Availability (HA)	1135
----------------------------------	-------------

25.1	Intro to HA in Canton	1135
25.1.1	Overview	1135
25.1.2	Active-Passive Participant Node Configuration	1138
25.1.3	HA on the Synchronization Domain	1141
25.2	HA for Production Systems	1143
25.2.1	HA and Horizontal Scaling	1144
25.2.2	High Availability From a Business Perspective	1144
25.2.3	Use Cases By Role	1148

28.3.1 Top-level Commands	1211
28.3.2 Participant Commands	1218
28.3.3 Multiple Participants	1272
28.3.4 Domain Administration Commands	1274
28.3.5 Domain Manager Administration Commands	1300
28.3.6 Sequencer Administration Commands	1313
28.3.7 Mediator Administration Commands	1319

29 Monitoring Best Practices	1326
29.1 Introduction	1326
29.1.1 Hands-On with the Daml Enterprise - Observability Example	1326
29.2 Golden Signals and Key Metrics Quick Start	1328
29.3 Set Up Metrics Scraping	1329
29.3.1 Enable the Prometheus Reporter	1329
29.3.2 Prometheus-Only Metrics	1329
29.3.3 Deprecated Reporters	1329
29.4 Metrics	1330
29.4.1 Participant Metrics	1330
29.4.2 Synchronization Domain Metrics	1358
29.4.3 Health Metrics	1373
29.4.4 gRPC Metrics	1373
29.4.5 HTTP Metrics	1374
29.4.6 Pruning Metrics	1375
29.4.7 JVM Metrics	1376
29.5 Logging	1377
29.5.1 Viewing Logs	1378
29.5.2 Detailed Logging	1378
29.6 Tracing	1379
29.6.1 Sampling	1379
29.6.2 Known Limitations	1380
29.6.3 Traces	1380
29.7 Node Health Status	1382
29.8 Health Checks	1383
29.8.1 gRPC Health Check Service	1383
29.8.2 HTTP Health Check	1384
29.9 Health Dumps	1384
29.9.1 Remote Health Dumps	1385
29.10 Example Monitoring Setup	1385
29.10.1 Container Setup	1385
29.10.2 Connecting to Nodes	1402
29.10.3 Kibana Log Monitoring	1403
29.10.4 Grafana Metric Monitoring	1404
29.10.5 Monitoring Choices	1405
29.10.6 Logging Improvements	1406
29.11 Glossary	1406
29.11.1 cAdvisor	1406
29.11.2 Docker Log Driver	1406
29.11.3 Docker Plugins	1406
29.11.4 ECS	1407

29.11.5 Elasticsearch	1407
29.11.6 ELK	1407
29.11.7 GELF	1407
29.11.8 Grafana	1407
29.11.9 Graylog	1407
29.11.10 Logstash	1408
29.11.11 Loki	1408
29.11.12 Loki Log Driver	1408
29.11.13 MinIO	1408
29.11.14 OpenTelemetry	1408
29.11.15 Prometheus	1408
29.11.16 Syslog	1409

30 PQS

1410

30.1 Introduction	1410
30.1.1 Audience	1410
30.1.2 Purpose	1411
30.1.3 Operational Architecture	1411
30.1.4 Key Feature Summary	1412
30.1.5 Sections	1412
30.2 Getting Started	1413
30.2.1 Pre-requisites	1413
30.2.2 Running PQS	1413
30.3 Database	1416
30.3.1 Ledger Source	1416
30.3.2 Transaction Data Source	1416
30.3.3 PostgreSQL Schema	1417
30.4 Configuration	1418
30.4.1 PQS Configuration	1418
30.4.2 Contract Filters	1420
30.4.3 Party Filtering	1420
30.4.4 Java Virtual Machine (JVM) Configuration	1420
30.4.5 PostgreSQL Configuration	1421
30.4.6 PostgreSQL Users	1422
30.4.7 Host Infrastructure	1422
30.4.8 Host Environment	1422
30.4.9 Testing	1422
30.5 Resilience	1423
30.5.1 High Availability	1423
30.5.2 Retries	1423
30.5.3 Ledger Streaming & Recovery	1427
30.6 Read API	1428
30.6.1 How The Ledger Models Time	1428
30.6.2 Time Model	1429
30.6.3 Offset Management	1430
30.6.4 JSONB Encoding	1432
30.6.5 Querying Patterns	1432
30.6.6 Summary functions	1434
30.6.7 Lookup functions	1435
30.6.8 Optimization	1436
30.7 Pruning	1439

30.7.1	Data Deletion and Changes	1439
30.7.2	Constraints	1440
30.7.3	Pruning from the command line	1440
30.7.4	Example with Timestamp and Duration	1440
30.7.5	Pruning from SQL	1441
30.8	Authentication	1441
30.8.1	Audience-Based Token	1442
30.8.2	Scope-Based Token	1442
30.8.3	Custom Daml Claims Tokens	1443
30.8.4	Static Access Token	1443
30.8.5	Ledger API Users and Daml Parties	1443
30.8.6	Token expiry	1443
30.9	History Slicing	1443
30.10	Reset Procedure	1445
30.10.1	Reset	1445
30.10.2	Constraints	1446
30.11	Logging	1446
30.11.1	Log Level	1446
30.11.2	Per-Logger Log Level	1446
30.11.3	Log Pattern	1446
30.11.4	Log Format for Console Output	1446
30.11.5	Log Format for File Output	1447
30.11.6	Destination File for File Output	1447
30.11.7	Log Format and Log Pattern Combinations	1447
30.12	Database Schema Evolution	1449
30.12.1	Baselining	1449
30.12.2	Schema Upgrades	1450
30.12.3	Schema Dump	1450
30.12.4	Monitoring Progress	1451
30.12.5	Troubleshooting	1452
30.12.6	Mapping Daml Models to Relational World	1456
30.12.7	Considerations	1463
30.12.8	Definitions	1464
30.12.9	Queries & Results	1465
30.12.10	Performance Optimizations	1469
30.12.11	Trade-Offs Summary	1478
30.13	Observability	1479
30.13.1	Underlying Mechanism	1479
30.13.2	Provided Metrics	1479
30.13.3	Example Dashboard	1483
30.13.4	Health Check	1485
30.13.5	Tracing of Pipeline Execution	1485
30.13.6	Trace Context Propagation	1492
30.14	Redaction	1493
30.14.1	Conditions for Redaction	1494
30.14.2	Examples	1494
30.14.3	Accessing Redaction Information	1494

31	Identity Management	1495
31.1	Introduction	1495
31.1.1	What is a Canton Identity?	1495

31.1.2	Unique Identifier	1496
31.1.3	Topology Transactions	1496
31.1.4	Legal Identities	1497
31.1.5	Life of a Party	1497
31.1.6	Participant Onboarding	1498
31.1.7	Default Initialization	1500
31.1.8	Identity Setup Guide	1501
31.2	User Identity Management	1502
31.3	Cookbook	1502
31.3.1	Manage Users	1502
31.3.2	Adding a new Party to a Participant	1507
31.3.3	Client Controlled Party	1507
31.3.4	Replicate Party to Another Participant Node	1509
31.3.5	Party on Multiple Nodes	1511
32	Common Operational Tasks	1513
32.1	Manage DARs and Packages	1513
32.1.1	Uploading DARs	1513
32.1.2	Inspecting DARs and Packages	1513
32.1.3	Understanding Package Vetting	1515
32.2	Upgrade To a New Release	1520
32.2.1	Upgrade Canton Binary	1521
32.2.2	Change the Canton Protocol Version	1531
32.2.3	One-Step Migration	1535
32.3	Security & Key Management	1536
32.3.1	Cryptographic Key Usage	1536
32.3.2	Cryptographic Key Management	1542
32.3.3	Ledger-API Authorization	1545
32.4	Key Management Service (KMS) Setup	1545
32.4.1	Canton Configuration of a KMS	1545
32.4.2	Configure Encrypted Private Key Storage with a Key Management Service (KMS)	1549
32.4.3	Configure External Key Storage with a Key Management Service (KMS)	1555
32.4.4	Canton KMS Driver Developer Guide	1565
33	Scaling and Performance	1576
33.1	Network Scaling	1576
33.2	Node Scaling	1577
33.3	Performance and Sizing	1578
33.4	Batching	1578
33.5	Asynchronous Submissions	1578
33.6	Storage Estimation	1578
33.7	Set Up Canton to Get the Best Performance	1580
33.7.1	System Design / Architecture	1580
33.7.2	Hardware and Database	1580
33.7.3	Configuration	1580
33.8	Model Tuning	1586
33.8.1	Reduce the Number of Views	1586
33.8.2	Reduce Ledger Events	1588
34	Advanced Ledger Operations	1590
34.1	Manage Synchronization Domains	1590
34.1.1	Permissioned Synchronization Domains	1590

34.1.2	Synchronization Domain Rules	1593
34.1.3	Dynamic synchronization domain parameters	1593
34.1.4	Recover From a Small Max Request Size	1594
34.2	Manage Synchronization Domain Entities	1595
34.2.1	Manual vs Automatic Initialization	1595
34.2.2	Keys Initialization	1596
34.2.3	Set up a Distributed Synchronization Domain With a Single Console	1598
34.2.4	Set Up a Distributed Synchronization Domain With Separate Consoles	1600
34.2.5	Add New Sequencers to a Distributed Synchronization Domain	1603
34.3	Manage Participants	1605
34.3.1	Manual vs Automatic Identity Initialization	1605
34.3.2	Keys Initialization	1605
34.3.3	Participant Manual Initialization	1606
34.4	Ledger Pruning	1607
34.4.1	Enable Automatic Pruning	1607
34.4.2	Schedule format	1608
34.4.3	Monitor Pruning Progress	1609
34.4.4	Best Practices	1609
34.4.5	Current Limitations	1610
34.5	Participant Pruning	1610
34.5.1	Impacts on Daml Applications	1611
34.5.2	How the Daml Ledger API is Affected	1611
34.5.3	Other Limitations	1612
34.5.4	How Pruning Affects Index DB Administration	1612
34.5.5	Determine a Suitable Pruning Offset	1613
34.6	Participant Metering	1613
34.6.1	Generate a Metering Report	1614
34.6.2	Example	1614
34.6.3	Output	1614
34.7	API Configuration	1615
34.7.1	Default Ports	1615
34.7.2	Administration API	1616
34.7.3	TLS Configuration	1616
34.7.4	Keep Alive	1618
34.7.5	Max Inbound Message Size	1619
34.7.6	Participant Configuration	1619
34.7.7	Synchronization Domain Configurations	1623
34.7.8	Usage of native libraries by Netty	1625
34.8	Sequencer Connections	1625
34.8.1	Participant Connections	1625
34.8.2	Mediator and Synchronization Domain Manager	1632
34.9	Repair Nodes	1633
34.9.1	Preparation	1634
34.9.2	Importing an actual Ledger	1634
34.9.3	Recovering from a Lost Synchronization Domain	1640
34.9.4	Repairing an actual Topology	1641
34.9.5	Clone Identity	1644
34.9.6	Importing Existing Contracts	1646
34.10	Decommissioning Canton Nodes and Sync Domain Entities	1646
34.10.1	Decommissioning a Participant Node	1646
34.10.2	Decommissioning a Sequencer	1649

34.10.3 Decommissioning a Mediator	1651
35 Troubleshooting Guide	1652
35.1 Introduction	1652
35.2 Enable Information Gathering	1652
35.3 Key Knowledge	1654
35.4 Log Files	1655
35.5 Using LNAV to View Log Files	1656
35.6 Setup Issues	1657
35.7 Timeout Errors	1658
35.8 Auth Errors	1658
35.9 Disconnections	1659
35.10 Performance Issues	1661
35.10.1 How to Measure Database Performance	1662
35.10.2 How to Diagnose Slow Database Queries	1662
35.10.3 How to find the Bottleneck	1663
35.11 Contention	1664
35.11.1 Why do you get contention	1664
35.11.2 How To Change Your Model To Avoid Undesired Contention	1665
35.11.3 How To Find Contention	1665
35.12 Use Bisection to Narrow Down the Root Cause	1666
36 Support Checklist	1668
36.1 Remote Console Access	1668
36.2 Logging	1669
36.3 Metrics	1670
36.4 Configuration and Patching	1670
36.5 Database Access	1670
37 Error Codes	1671
37.1 Overview	1671
37.2 Glossary	1671
37.3 Anatomy of an Error	1672
37.3.1 Error Description	1672
37.3.2 Additional Machine-Readable Information	1672
37.3.3 Prevent Security Leaks in Error Codes	1673
37.3.4 Work With Error Codes	1673
37.4 Error Codes In Canton Operations	1674
37.5 Error Categories	1675
37.6 Machine Readable Information	1675
37.7 Example	1676
37.8 Error Categories Inventory	1676
37.8.1 TransientServerFailure	1677
37.8.2 ContentionOnSharedResources	1677
37.8.3 DeadlineExceededRequestStateUnknown	1677
37.8.4 SystemInternalAssumptionViolated	1678
37.8.5 AuthInterceptorInvalidAuthenticationCredentials	1678
37.8.6 InsufficientPermission	1678
37.8.7 SecurityAlert	1679
37.8.8 InvalidIndependentOfSystemState	1679
37.8.9 InvalidGivenCurrentSystemStateOther	1679
37.8.10 InvalidGivenCurrentSystemStateResourceExists	1680

37.8.11	InvalidGivenCurrentSystemStateResourceMissing	1680
37.8.12	InvalidGivenCurrentSystemStateSeekAfterEnd	1680
37.8.13	BackgroundProcessDegradationWarning	1681
37.8.14	InternalUnsupportedOperation	1681
37.9	Error Codes Inventory - Daml	1681
37.9.1	1. ParticipantErrorGroup	1681
37.9.2	1.1. ParticipantErrorGroup / CommonErrors	1681
37.9.3	1.2. ParticipantErrorGroup / IndexErrors	1683
37.9.4	1.2.1. ParticipantErrorGroup / IndexErrors / DatabaseErrors	1683
37.9.5	1.3. ParticipantErrorGroup / LedgerApiErrors	1683
37.9.6	1.3.1. ParticipantErrorGroup / LedgerApiErrors / AdminServices	1684
37.9.7	1.3.1.1. ParticipantErrorGroup / LedgerApiErrors / AdminServices / IdentityProviderConfigServiceErrorGroup	1684
37.9.8	1.3.1.2. ParticipantErrorGroup / LedgerApiErrors / AdminServices / PartyManagementServiceErrorGroup	1685
37.9.9	1.3.1.3. ParticipantErrorGroup / LedgerApiErrors / AdminServices / UserManagementServiceErrorGroup	1686
37.9.10	1.3.2. ParticipantErrorGroup / LedgerApiErrors / AuthorizationChecks	1687
37.9.11	1.3.3. ParticipantErrorGroup / LedgerApiErrors / CommandExecution	1688
37.9.12	1.3.3.1. ParticipantErrorGroup / LedgerApiErrors / CommandExecution / Interpreter	1688
37.9.13	1.3.3.1.1. ParticipantErrorGroup / LedgerApiErrors / CommandExecution / Interpreter / LookupErrors	1692
37.9.14	1.3.3.2. ParticipantErrorGroup / LedgerApiErrors / CommandExecution / Preprocessing	1692
37.9.15	1.3.4. ParticipantErrorGroup / LedgerApiErrors / ConsistencyErrors	1693
37.9.16	1.3.5. ParticipantErrorGroup / LedgerApiErrors / PackageServiceError	1694

Chapter 1

Introduction To Multi-Party Applications and Daml

1.1 Multi-Party Applications

Multi-party applications, and multi-party application platforms like Daml, solve problems that were near

- why multi-party applications matter
- what a multi-party application is
- important concepts in multi-party applications
- key architectural concepts in Daml
- a transfer example using Daml

1.2 Why Do Multi-Party Applications Matter?

Have you ever wondered why bank transfers, stock purchases or healthcare claims take days to process? Given our technological advances, including the speed of networks, you might expect these transactions to take less than a second to complete. An inefficient protocol like email takes only a few seconds to send and receive, while these important business workflows take days or weeks.

What delays these transactions? The processes in question all involve multiple organizations that each keep their own records, resulting in data silos. The processes to ensure consistency between those data silos are complex and slow. When inconsistencies arise, the correction processes (sometimes referred to as reconciliation) are expensive, time-consuming and often require human intervention to determine why two parties have differing views of the result of a business interaction. There are a myriad of reasons for these discrepancies, including differences in data models and error handling logic, inconsistent business process implementations and system faults.

Here's a deeper look at the problem via the example of a transfer of \$100 from Alice's account in Bank A to Bob's account in Bank B. (Money is an easily understood example of an asset transferred between parties. The same problems occur in other industries with other assets, for example, healthcare claims, invoices or orders.) Money cannot simply appear or disappear during a transfer. The banks need to ensure that at some point in time, T_0 , \$100 are in Alice's account, and at the next point in time, T_1 , those \$100 are gone from Alice's account and present in Bob's account – but at no point are the \$100 present in both accounts or in neither account.

In legacy systems, each bank keeps track of cash holdings independently of the other banks. Each bank stores data in its own private database. Each bank performs its own processes to validate, secure, modify and regulate the workflows that transfer money. The coordination between multiple banks is highly complex. The banks have an obligation to limit their counterparty risk - the probability that the other party in the transaction may not fulfill its part of the deal and may default on the contractual obligations.

Today's common, albeit highly inefficient and costly, solution for a bank account transfer involves the following steps:

1. Bank A sends a message to Bank B via a messaging standard and provider like SWIFT or SEPA.
2. Bank A and Bank B determine a settlement plan, possibly including several intermediaries. Gaining an agreement on the settlement plan is time-consuming and often includes additional fees.
3. The settlement process entails (i) debiting \$100 from Alice's account at Bank A, (ii) crediting the commercial account at Bank B, and (iii) once Bank B has the money, crediting Bob's account at Bank B.

In order to make this process atomic (that is, to make it take place between a point T_0 and a point T_1) banks discretize time into business days. On day T_0 the instruction is made and a settlement plan is created. Outside of business hours between day T_0 and day T_1 , the plan is executed through end of day netting and settlement processes. In a sense, banks agree to stop time outside of business hours.

If intermediaries are involved, the process is more complex. Cross-border payments or currency conversion add yet more complexity. The resulting process is costly and takes days. During this multi-day process the \$100 is locked within the system where it is useless to both Alice and Bob. Delays are common, and if there are problems reconciliation is hugely expensive. Consolidating through centralized intermediaries introduces systemic risk, including the risk of unauthorized disclosure and privacy breaches - and with that risk comes increased latency. Banks insist on this approach, despite the downsides, to reduce counterparty risk and to comply with regulations. At every point in time, ownership of the money is completely clear. (To learn more about cash transfers in traditional banking systems, read [this accessible writeup on international money transfers](#).)

Services like PayPal, Klarna and credit cards, which provide an experience of instant payments internationally, do this by accepting the counterparty risk or acting as banks themselves. If a shop accepts credit cards and you pay with a credit card, both you and the shop have an account with the credit card company. When you purchase, the credit card company can instantly debit \$100 from your account and credit \$100 to the shop's account because it is as if both Alice and Bob are using accounts at the same bank - the bank is certain that Alice has \$100 in her account and can execute a simple transaction that deducts \$100 from Alice's account and adds \$100 to Bob's.

Wouldn't it be great if a system existed that allowed multiple parties to transact with each other with the same immediacy and consistency guarantees a single organization can achieve on a database while each kept sovereignty and privacy of their data? That's Daml!

Daml is a platform and framework for building real-time multi-party systems, enabling organizations to deliver the experiences modern users expect without assuming counterparty risk or the expense of reconciliation. The sections below describe how Daml achieves this, including the architectural concepts and considerations necessary to build and deploy a solution with Daml effectively.

1.3 What Is a Multi-Party Application?

A multi-party application is one in which data, and the rules and workflows that govern the data, are shared between two or more parties without any party having to give up sovereignty or any single party (including the application provider) being able to control or override the agreed rules of the system. A party could be a company, a department within a company, an organization, an individual or a person. The specific definition of a party will be unique to the application and the domain of that application.

A well-designed multi-party application provides several benefits:

- a clean, consistent view of all data managed by the application across all parties
- consistent, connected, and efficient processes between all parties involved in the application
- privacy controls over portions of the shared data, such that each party sees only the data that it is explicitly entitled to view and/or modify
- individual party ownership of and responsibility for sensitive data

In most cases, no single party can view all of the data within a multi-party application.

Multi-party applications solve complex operational processes while keeping data clean and consistent, thereby eliminating isolated, disconnected and inefficient processes that often require expensive reconciliation. Multi-party applications manage the relationships, agreements and transactions between parties, providing consistent real-time views of all data.

Multi-party solutions utilize distributed ledger (blockchain) technology to ensure each party has an immutable, consistent view of the shared data and business processes that govern the data. By providing a consistent view of data with all counterparties, a multi-party application removes friction, cost, and risk within a joint business process. A distributed ledger protects against a malicious participant in the network, attempting to write or overwrite data to the detriment of other parties.

1.4 Important Concepts in Multi-Party Applications

For a multi-party application to fully deliver its value, the following conditions must be met:

Multiple involved parties have data sovereignty – that is, they keep their data within their own systems and require strong guarantees that no external party can access or modify that data outside of pre-agreed rules. Shared state and rules are codified into an executable schema that determines what data can move between parties, who can read that data, and how that data is manipulated. Processes happen in real time as there is no additional reconciliation or manual processing required between organizations.

For each individual party to gain the full benefits of a multi-party system, it should:

- Integrate the application - Bank A must treat the multi-party infrastructure as the golden source of truth for payment information and integrate it as such with the rest of their infrastructure. Otherwise they are merely trading inter-bank reconciliation for intra-bank reconciliation.
- Utilize composability by building advanced systems that rely on the base-level multi-party agreements. For example, a healthcare claim application should be built using the payment solution. Integrating one multi-party application with another preserves all the properties of each across both applications. In this example, the patient privacy requirements of a health claims application are retained, as are the financial guarantees of the

payment application. Without composability, multi-party applications become bigger silos and you end up reconciling the healthcare claims multi-party application with the payments multi-party application.

Smart contracts, distributed ledgers, and blockchains are commonly used to build and deliver multi-party applications. A smart contract codifies the terms of the agreement between parties, including the rights and obligations of each party, directly written into lines of code. The code controls the execution, and transactions are trackable and irreversible. In a multi-party application, the smart contract defines the data workflow through actions taken by the parties involved.

Distributed ledgers and blockchains provide consensus between the parties, with a cryptographic audit trail maintained and validated by the system. Within multi-party solutions, the distributed ledger ensures no one party can unilaterally change the system's state and protects data sovereignty, while the distributed ledger synchronizes the nodes securely in real time.

1.5 Key Architectural Concepts in Daml

Daml comprises two layers necessary for building multi-party applications: the Daml smart contract language and the Canton blockchain and protocol.

The Daml language is a smart contract language for multi-party applications. Conceptually, Daml is similar to the Structured Query Language (SQL) used in traditional database systems, describing the data schema and rules for manipulating the data.

The Daml language:

- defines the shared state between the parties, including process permissions and data ownership
- defines workflows, execution policies, and read/write permissions
- enables developers to build rich transactions that codify strict business rules
- defines the APIs through which multi-party applications can talk to each other and compose

The Daml code that collectively makes up the data schema and rules for an application is called a Daml model. Increasingly sophisticated and valuable solutions are composed from existing Daml models, enabling a rich ecosystem that accelerates application development.

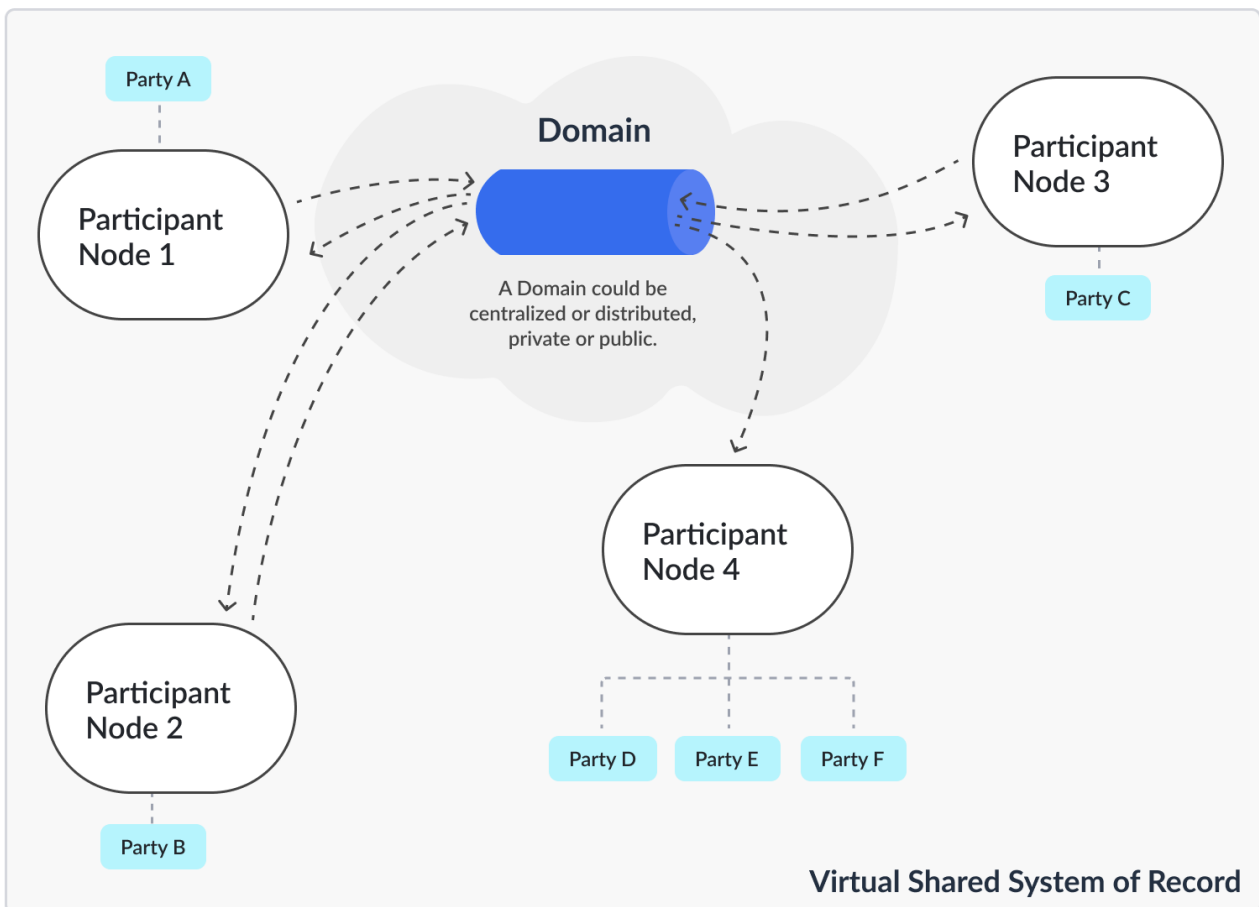

Using the Daml language, developers define the schema for a virtual shared system of record (VSSR). A VSSR is the combined data from all parties involved in the application. The Canton protocol ensures that each party gets a unique view into the VSSR, which is their projection of the full system.

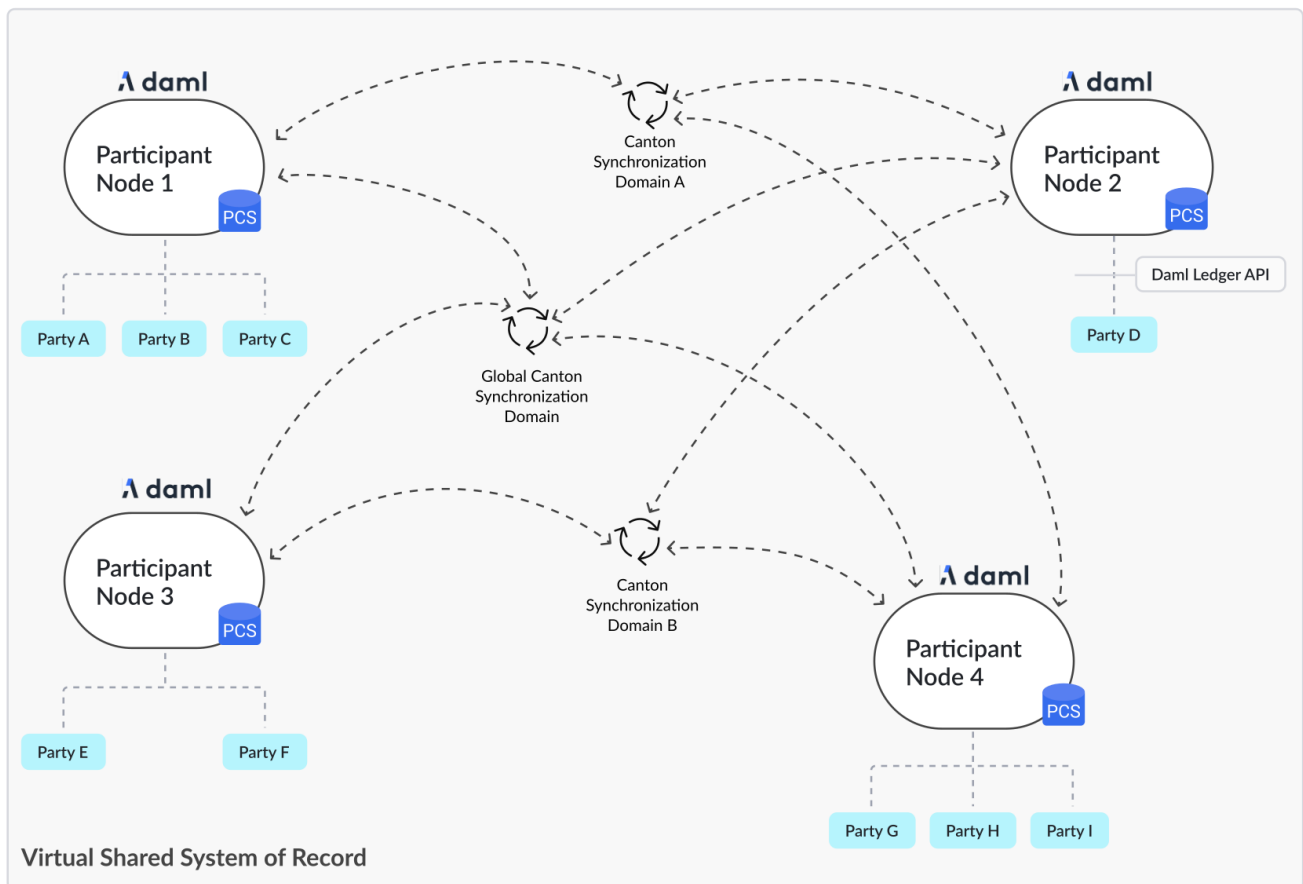

In the execution model for Canton, each party of the application is hosted on a Participant Node (Diagram 1). The Participant Node stores the party's unique projection and history of the shared system of record. Participant Nodes synchronize by running a consensus protocol (the Canton Protocol) between them. The protocol is executed by sending encrypted messages through sync domains, which route messages and offer guaranteed delivery and order consistency. Sync domains are also units of access control and availability, meaning an application can be additionally protected from interference by other applications or malicious actors by synchronizing it only through a given sync domain, and restricting which participants can connect to it.

Diagram 1:

In a composed solution, each sync domain is a sub-network. A participant node connects to one or more sync domains, enabling transactions that span sync domains (Diagram 2).

Diagram 2:

1.6 Transfer Example Using Daml

Consider the transfer example described above with Alice and Bob. Using Daml, the process looks like this:

1. Alice logs into her online banking at Bank A and enters a transfer to Bob at Bank B.
2. The online banking backend creates a transaction that deducts \$100 from Alice's account and creates a transfer to Bob at Bank B.
3. When Bank B accepts the transfer, Bank A credits \$100 to Bank B's account at Bank A and Bank B simultaneously credits Bob's account by \$100.
4. Bob's online banking interfaces with the Daml Ledger and can see the incoming funds in real time.

At every point, ownership of the \$100 is completely clear and all systems are fully consistent.

1.7 Next Steps

The suggested next steps are:

Learn about the Daml language and the Daml Ledger Model. [Writing Daml](#) will introduce you to the basics of a Daml contract, the Daml Ledger model, and the core features of the Daml language. You'll notice that testing your contracts, including [testing for failures](#), is presented very early in this introduction. We strongly recommend that you write tests as part of the initial development of every Daml project.

Learn about operating a Daml application with the [Ledger Administration Introduction](#).

Chapter 2

System Requirements

Unless otherwise stated, all Daml runtime components require the following:

1. For development, one of:
 - x86-compatible systems running a modern Linux or Windows operating system
 - ARM-based Macintosh systems running MacOS 11 or above
 - Deprecated: Intel-based Macintosh systems
2. For production deployment, an x86-compatible system running a modern Linux operating system
3. Java 11 or later
4. An RDBMS system, *either*:
 - PostgreSQL 11.17-15 (12+ recommended)
 - or
 - Oracle Database 19.11 or later
5. JDBC drivers compatible with your RDBMS

In terms of hardware requirements for development, a simple Daml application can run with a laptop using 2 GB of memory and a couple of CPU cores. However, [a much larger environment](#) is recommended for testing or production use.

Please note that the deprecated Intel-based MacIntosh binaries are produced on a best effort basis. At some future point, a lack of Intel Mac machines may preclude building Intel binaries which will result in Intel-based MacIntosh support changing to unsupported and unavailable.

2.1 Feature/Component System Requirements

[The JavaScript client libraries](#) are tested on Node 14.18.3 with TypeScript compiler 4.5.4. For best results, use these or later versions.

Chapter 3

Install the SDK

3.1 Install the Dependencies

The Daml SDK currently runs on Windows, macOS and Linux.

You need to install:

1. [Visual Studio Code](#).
2. JDK 11 or greater. If you don't already have a JDK installed, try [Eclipse Adoptium](#).
As part of the installation process you may need to set up the `JAVA_HOME` variable. You can find instructions for this process on [Windows, macOS, and Linux here](#).

3.2 Choose Daml Enterprise or Daml Open Source

Daml comes in two variants: Daml Enterprise or Daml Open Source. Both include the best in class SDK, Canton and all of the components that you need to write and deploy multi-party applications in production, but they differ in terms of enterprise and non-functional capabilities:

Capability	Enterprise	Open Source
Sub-Transaction Privacy	Yes	Yes
Transaction Processing	Parallel (fast)	Sequential (slow)
High Availability	Yes	No
Horizontal scalability	Yes	No
Ledger Pruning	Yes	No
Local contract store in PostgreSQL	Yes	Yes
Local contract store in Oracle	Yes	No
PostgreSQL driver	Yes	Yes
Oracle driver	Yes	No
Besu driver	Yes	No
Fabric driver	Yes	No
Profiler	Yes	No
Non-repudiation Middleware	Yes (early access)	No

3.3 Install Daml Open Source SDK

3.3.1 Windows 10

Download and run the [installer](#), which will install Daml and set up the PATH variable for you.

3.3.2 Mac and Linux

Open a terminal and run:

```
curl -sSL https://get.daml.com/ | sh
```

The installer will setup the PATH variable for you. In order for it to take effect, you will have to log out and log in again.

If the `daml` command is not available in your terminal after logging out and logging in again, you need to set the PATH environment variable manually. You can find instructions on how to do this [here](#).

3.4 Install Daml Enterprise

If you have a license for Daml Enterprise, you can install it as follows:

On Windows, download the installer from [Artifactory](#) instead of Github releases.

On Linux and MacOS, download the corresponding tarball, extract it, and run `./install.sh`. Afterward, modify the [global daml-config.yaml](#) to add an entry for your Artifactory token. The Daml Enterprise tooling accepts either an Artifactory API key or an Artifactory identity token, but API keys are deprecated by Artifactory as of the end of 2023. To manage API keys and identity tokens, go to your [Artifactory profile page](#).

```
artifactory-api-key: YOUR_API_KEY
```

This will be used by the assistant to download other versions automatically from Artifactory. The config key is called `artifactory-api-key` for historical reasons, but you can use either an identity token or an API key.

If you already have an existing installation, you only need to add this entry to `daml-config.yaml`. To overwrite a previously installed version with the corresponding Daml Enterprise version, use `daml install --force VERSION`.

3.5 Download Manually

If you want to verify the SDK download for security purposes before installing, you can look at [our detailed instructions for manual download and installation](#).

3.6 Next Steps

Follow the [getting started guide](#).

Use `daml --help` to see all the commands that the Daml assistant (`daml`) provides.

If you run into any other problems, you can use the [support page](#) to get in touch with us.

Chapter 4

Set JAVA_HOME and PATH Variables

4.1 Windows

To set up `JAVA_HOME` and `PATH` variables on Windows:

4.1.1 Set the JAVA_HOME Variable

1. Search for Advanced System Settings (open Search, type `advanced system settings` and hit Enter).
2. Find the Advanced tab and click Environment Variables.
3. Click New in the System variables section (if you want to set `JAVA_HOME` system wide) or in the User variables section (if you want to set `JAVA_HOME` for a single user). This will open a modal window for Variable name.
4. In the Variable name window type `JAVA_HOME`, and for the Variable value set the path to the JDK installation.
5. Click OK in the Variable name window.
6. Click OK in the tab and click Apply to apply the changes.

4.1.2 Set the PATH Variable

The `PATH` variable is automatically set by the [Windows installer](#).

4.2 Mac OS

First, determine whether you are running Bash or zsh. Open a Terminal and run:

```
echo $SHELL
```

This should return either `/bin/bash`, in which case you are running Bash, or `/bin/zsh`, in which case you are running zsh.

If you get any other output, you have a non-standard setup. If you're not sure how to set up environment variables in your setup, ask on the [Daml forum](#) and we will be happy to help.

Open a terminal and run the following commands. Copy/paste one line at a time if possible. None of these should produce any output on success.

To set the variables in **bash**:

```
echo 'export JAVA_HOME="$ (/usr/libexec/java_home) "' >> ~/.bash_profile
echo 'export PATH="$HOME/.daml/bin:$PATH"' >> ~/.bash_profile
```

To set the variables in **zsh**:

```
echo 'export JAVA_HOME="$ (/usr/libexec/java_home) "' >> ~/.zprofile
echo 'export PATH="$HOME/.daml/bin:$PATH"' >> ~/.zprofile
```

For both shells, the above will update the configuration for future, newly opened terminals, but will not affect any existing one.

To test the configuration of `JAVA_HOME` (on either shell), open a new terminal and run:

```
echo $JAVA_HOME
```

You should see the path to the JDK installation, which is something like `/Library/Java/JavaVirtualMachines/jdk_version_number/Contents/Home`.

Next, please verify the `PATH` variable by running (again, on either shell):

```
daml version
```

You should see the header `SDK versions:` followed by a list of installed (or available) SDK versions (possibly a list of just one if you just installed).

If you do not see the expected outputs, contact us on the [Daml forum](#) and we will be happy to help.

4.3 Linux

To set up `JAVA_HOME` and `PATH` variables on Linux for `bash`:

4.3.1 Set the `JAVA_HOME` Variable

Java is typically installed in a folder like `/usr/lib/jvm/java-version`. Before running the following command make sure to change the `java-version` with the actual folder found on your computer:

```
echo "export JAVA_HOME=/usr/lib/jvm/java-version" >> ~/.bash_profile
```

4.3.2 Set the PATH Variable

The installer will ask to set the `PATH` variable for you. If you want to set the `PATH` variable manually instead, run the following command:

```
echo 'export PATH="$HOME/.daml/bin:$PATH"' >> ~/.bash_profile
```

4.3.3 Verify the Changes

In order for the changes to take effect you will need to restart your computer. After the restart, verify that everything was set up correctly using the following steps:

Verify the `JAVA_HOME` variable by running:

```
echo $JAVA_HOME
```

You should see the path you gave for the JDK installation, which is something like `/usr/lib/jvm/java-version`.

Then verify the `PATH` variable by running:

```
echo $PATH
```

You should see a series of paths which includes the path to the SDK, which is something like `/home/your_username/.daml/bin`.

Chapter 5

Manual Installation

The default way to install the SDK is to run:

```
curl https://get.daml.com | sh
```

However, there are some contexts in which this is not the best option, such as when the machine you want to install the Daml SDK on does not have full access to the internet, or if you are not comfortable executing scripts directly from the internet.

This page covers two topics:

1. Installing the SDK from a downloaded tarball.
2. Verifying the integrity of a downloaded tarball.

5.1 Install the SDK from a Tarball

Tarballs for the Open Source Edition of the Daml SDK can be downloaded [from GitHub](#); tarballs for the Enterprise Edition can be downloaded [from Artifactory](#).

SDK tarballs bear the SDK version string. When installing from a tarball, you need to know both the SDK version string and the Daml version string. For stable releases up to and including 2.8.0, they are the same, but this may not always be the case in snapshots or later versions.

Once you have a tarball, extract it and run the install script (unless you chose the Windows installer, in which case double-click the installer icon). Supply the Daml version string using the `--install-with-custom-version` flag. For example, for version 2.8.0:

```
tar xzf daml-sdk-2.8.0-macos.tar.gz
cd sdk-2.8.0
./install.sh --install-with-custom-version 2.8.0
```

Note that in the above command the SDK and Daml version strings are identical (2.8.0), which may make it a bit trickier to see which is which. In the case of a snapshot, such as [2.8.0-snapshot.20231122.0](#), the SDK version string, `2.8.0-snapshot.20231118.12382.0.v86cb8054`, and the Daml version string, `2.8.0-snapshot.20231122.0`, differ. The commands would become:

```
tar xzf daml-sdk-2.8.0-snapshot.20231118.12382.0.v86cb8054-macos.tar.gz
cd sdk-2.8.0-snapshot.20231118.12382.0.v86cb8054
./install.sh --install-with-custom-version 2.8.0-snapshot.20231122.0
```

Just like for the standard installation procedure, you may want to add `~/ .daml/bin` to your `$PATH`.

5.2 Verify the Integrity of a Tarball

If you require a higher level of security, you can instead install the Daml SDK by manually downloading the compressed tarball, verifying its signature, extracting it and manually running the install script.

Note that the Windows installer is already signed (within the binary itself), and that signature is checked by Windows before starting it. Nevertheless, you can still follow the steps below to check its external signature file.

To do that:

1. Go to [GitHub](#) for the Open Source Edition, or [Artifactory](#) for the Enterprise Edition. In either case, confirm that your browser sees a valid certificate for the domain.
2. Find the appropriate release and note the release name. Stable releases have names like `2.8.0`. Snapshots have names like `2.8.0-snapshot.20231129.0`.
3. Download the artifact for your platform as well as the corresponding signature file, which has the same name with an added `.asc` at the end. For example, if you are on macOS and are looking at the Open Source Edition you would download the files `daml-sdk-<...>-macos.tar.gz` and `daml-sdk-<...>-macos.tar.gz.asc`. On GitHub, the artifact and signature file are found in the Assets section, after the release notes.

Note: You can safely ignore the version string in the tarball name - this is an internal version string that is superseded by the version you took note of in step 2. If you are installing a stable release, this internal version will be the same as the release version you took note of. If it is a snapshot, the `<...>` section will be different.

For Windows you can choose between the tarball (ends in `.tar.gz`), which follows the same instructions as the Linux and macOS ones (but assumes you have a number of typical Unix tools installed), or the installer, which ends with `.exe`. Regardless, the steps to verify the signature are the same.

4. To verify the signature, you need to have `gpg` installed (see <https://gnupg.org> for more information on that) and the Digital Asset Security Public Key imported into your keychain. Once you have `gpg` installed, you can import the key by running:

```
gpg --keyserver hkp://pgp.mit.edu --search
→ F26D8A0AADF666CCB28F2AB1650EC3253B6A8FF5
```

This should come back with a key belonging to Digital Asset Holdings, LLC `<security@digitalasset.com>`, created on 2023-01-10 and expiring on 2025-01-09. If any of those details are different, something is wrong. In that case please contact Digital Asset immediately.

Alternatively, if key servers do not work for you (we are having a bit of trouble getting them to work reliably for us), you can find the full public key at the bottom of this page.

5. Once the key is imported, you can ask `gpg` to verify that the file you have downloaded has indeed been signed by that key. Continuing with our example of 2.8.0 on macOS, you should have both files in the current directory and run:

```
gpg --verify daml-sdk-2.8.0-macos.tar.gz.asc
```

and that should give you a result that looks like:

```

gpg: assuming signed data in 'daml-sdk-2.8.0-linux.tar.gz'
gpg: Signature made Fri 15 Dec 2023 15:53:57 GMT
gpg:                using RSA key CADC3D1E3B5C4C5F94A65D78A7BF65AAADBBC494
gpg: Good signature from "Digital Asset Holdings, LLC <security@digitalasset.
  ↪com>" [unknown]
gpg: WARNING: This key is not certified with a trusted signature!
gpg:                There is no indication that the signature belongs to the owner.
Primary key fingerprint: F26D 8A0A ADF6 66CC B28F  2AB1 650E C325 3B6A 8FF5
Subkey fingerprint: CADC 3D1E 3B5C 4C5F 94A6  5D78 A7BF 65AA ADBB C494

```

Note: This warning means you have not told gnupg that you trust this key actually belongs to Digital Asset. The [unknown] tag next to the key has the same meaning: gpg relies on a web of trust, and you have not told it how far you trust this key. Nevertheless, at this point you have verified that this is indeed the key that has been used to sign the archive.

To import the public key directly without relying on a keyserver, you can copy-paste the following Bash command:

```

gpg --import < <(cat <<EOF

Chapter 6

Getting Started with Daml

The goal of this tutorial is to get you up and running with full-stack Daml development. Through the example of a simple social networking application, you will learn:

1. How to build and run the application
2. The design of its different components ([App Architecture](#))
3. How to write a new feature for the app ([Your First Feature](#))

The goal is that by the end of this tutorial, you'll have a good idea of the following:

- What Daml contracts and ledgers are
- How a user interface (UI) interacts with a Daml ledger
- How Daml helps you build a real-life application fast.

This is not a comprehensive guide to all Daml concepts and tools or all deployment options; these are covered in-depth in the User Guide. **For a quick overview of the most important Daml concepts used in this tutorial you can refer to [the Daml cheat-sheet](#).**

With that, let's get started!

6.1 Prerequisites

Make sure that you have the Daml SDK, Java 11 or higher, and Visual Studio Code (the only supported IDE) installed as per the instructions in [Install the SDK](#).

You will also need some common software tools to build and interact with the template project:

- [Node](#) and the associated package manager `npm`. Use the [Active LTS](#) Node version, currently `v18` (check with `node --version`).
- A terminal application for command line interaction.

6.2 Run the App

To get the app up and running:

1. Open a terminal, select a folder in which to create your first application, and instantiate the template project.

```
daml new create-daml-app --template create-daml-app
```

This creates a new folder with contents from our template. To see a list of all available templates run `daml new --list`.

2. Change to the new folder:

```
cd create-daml-app
```

3. Open two terminal windows.
4. In one terminal, at the root of the `create-daml-app` directory, run the command:

```
daml start
```

Any commands starting with `daml` are using the [Daml Assistant](#), a command line tool in the SDK for building and running Daml apps.

The command has started successfully when you see the `INFO com.daml.http.Main$ - Started server: ServerBinding(/127.0.0.1:7575)` message in the terminal. The command does a few things:

1. Compiles the Daml code to a DAR (Daml Archive) file
2. Generates a JavaScript library in `ui/daml.js` to connect the UI with your Daml code
3. Starts an instance of the [Sandbox](#), an in-memory ledger useful for development, loaded with our DAR
4. Starts a server for the [HTTP JSON API](#), a simple way to run commands against a Daml ledger (in this case the running Sandbox)

We'll leave these processes running to serve requests from our UI.

5. In the second terminal, navigate to the `create-daml-app/ui` folder and use `npm` to install the project dependencies:

```
cd create-daml-app/ui
npm install
```

This step may take a couple of moments. You should see `success Saved lockfile.` in the output if everything worked as expected.

6. Start the UI with:

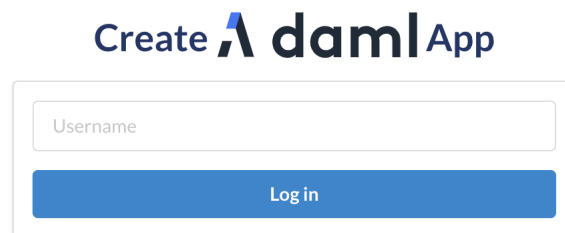

```
npm start
```

This starts the web UI connected to the running Sandbox and JSON API server. The command should automatically open a window in your default browser at <http://localhost:3000>.

Once the web UI has been compiled and started, you should see `Compiled successfully!` in your terminal. If you don't, open <http://localhost:3000> in a web browser. Depending on your firewall settings, you may be asked whether to allow the app to receive network connections. It is safe to accept.

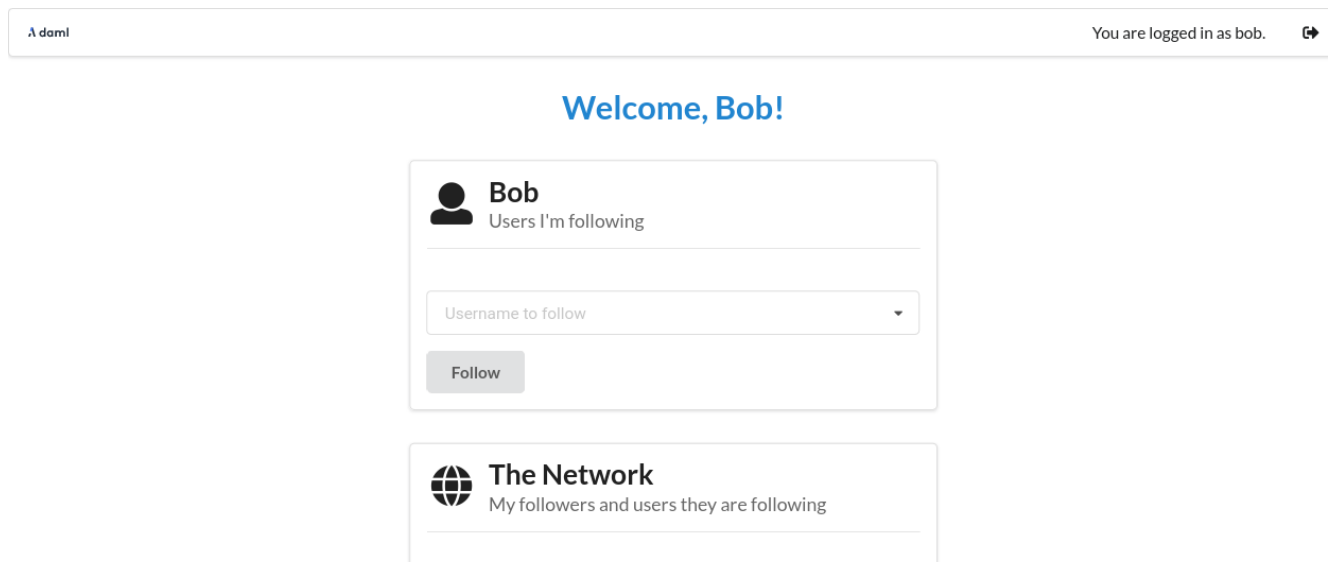

You should now see the login page for the social network. For simplicity, in this app there is no password or sign-up required.

1. Enter a user name. Valid user names are bob, alice, or charlie (note that these are all lower-case, although they are displayed in the social network UI by their alias instead of their user id, with the usual capitalization).
2. Click *Log in*.

The login form is titled "Create A damlApp". It contains a text input field labeled "Username" and a blue button labeled "Log in".

You should see the main screen with two panels. The top panel displays the social network users you are following; the bottom displays the aliases of the users who follow you. Initially these are both empty as you are not following anyone and you don't have any followers. To start following a user, select their name in the drop-down list and click the *Follow* button in the top panel. At the moment, you will notice that the drop-down shows only your own user because no other user has registered yet.

The main screen has a header bar with "A daml" on the left and "You are logged in as bob." with a user icon on the right. Below the header, the text "Welcome, Bob!" is displayed. The main content area contains two panels. The top panel, titled "Bob" with a user icon, is labeled "Users I'm following" and contains a drop-down menu labeled "Username to follow" and a "Follow" button. The bottom panel, titled "The Network" with a globe icon, is labeled "My followers and users they are following".

Next, open a new browser window/tab at <http://localhost:3000> and log in as a different user. (Having separate windows/tabs allows you to see both your own screen and the screen of the user you are following at the same time.)

Now that the other user (Alice in this example) has logged in, go back to the previous window/tab, select them drop-down list and click the *Follow* button in the top panel.

The user you just started following appears in the *Following* panel. However, they do not yet appear

in the *Network* panel. This is because they have not yet started following you. This social network is similar to Twitter and Instagram, where by following someone, say Alice, you make yourself visible to her but not vice versa. We will see how we encode this in Daml in the next section.

To make this relationship reciprocal, go back to the other window/tab where you logged in as the second user (Alice in this example). You should now see your name in her network. In fact, Alice can see the entire list of users you are following in the *Network* panel. This is because this list is part of the user data that became visible when you started following her.

When Alice starts following you, you can see her in your network as well. Switch to the window where you are logged in as yourself - the network should update automatically.

Play around more with the app at your leisure: create new users and start following more users. Observe when a user becomes visible to others - this will be important to understanding Daml's privacy model later. When you're ready, let's move on to the [architecture of our app](#).

Tip: Congratulations on completing the first part of the Getting Started Guide! [Join our forum](#) and share a screenshot of your accomplishment to [get your first of 3 getting started badges](#)! You can get

A daml

You are logged in as bob. **Welcome, Bob!**

 **Bob**
Users I'm following

 Alice

 Follow

 **The Network**
My followers and users they are following

 Alice

 Bob

the next one by *implementing your first feature*.

Chapter 7

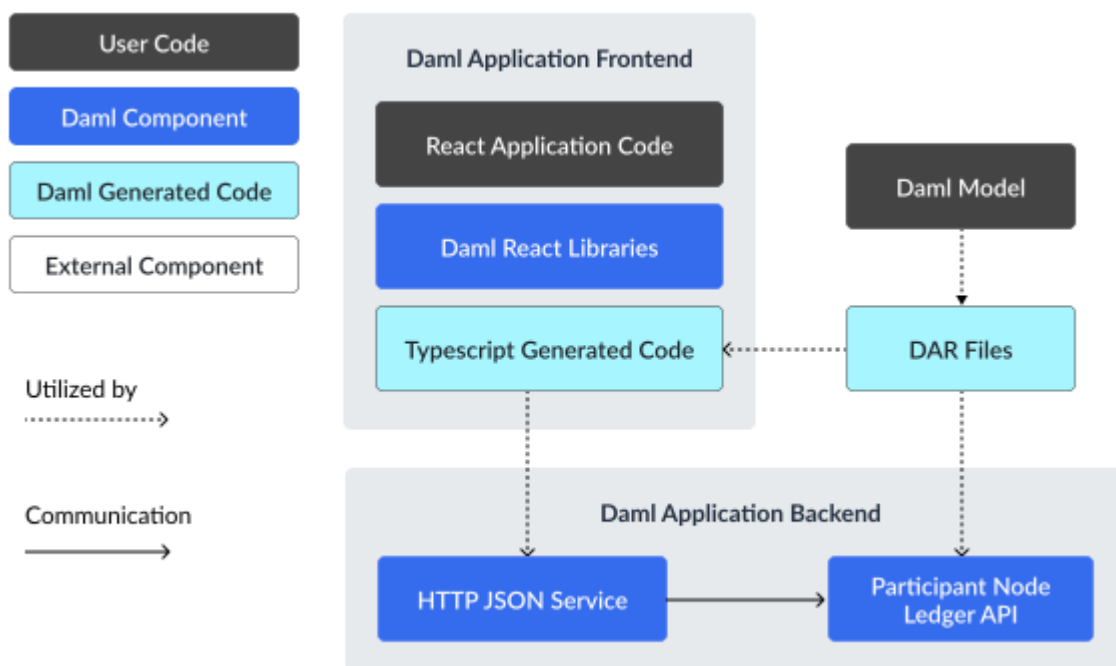

App Architecture

In this section we'll look at the different components of the social network app we created in [Building Your App](#). The goal is to familiarize yourself with the basics of Daml architecture enough to feel comfortable extending the code with a new feature in the next section. There are two main components:

- the Daml model
- the React/TypeScript frontend

We generate TypeScript code to bridge the two.

Overall, the social networking app follows the [recommended architecture of a fullstack Daml application](#). Below is a simplified version of the architecture represented in the app.

There are four types of building blocks that go into our application: user code, generated code from Daml, Daml components, and external components. The Daml model determines the DAR files that underpin both the frontend and backend. The frontend includes React application code, Daml React libraries, and Typescript generated code. From the client point of view, the backend consists of the JSON API and a participant node.

Let's start by looking at the Daml model, which defines the core logic of the application. Have [the Daml cheat-sheet](#) open in a separate tab for a quick overview of the most common Daml concepts.

7.1 The Daml Model

In your terminal, navigate to the root `create-daml-app` directory and run:

```
daml studio
```

This should open the Visual Studio Code editor at the root of the project. (You may get a new tab pop up with release notes for the latest version of Daml - close this.) Using the file Explorer on the left sidebar, navigate to the `daml` folder and double-click on the `User.daml` file.

The Daml code defines the *data* and *workflow* of the application. Both are described in the `User` contract template. Let's look at the data portion first:

```
template User with
  username: Party
  following: [Party]
where
  signatory username
  observer following
```

There are two important aspects here:

1. The data definition (a schema in database terms), describing the data stored with each user contract. In this case it is an identifier for the user and the list of users they are following. Both fields use the built-in `Party` type which lets us use them in the following clauses.
2. The signatories and observers of the contract. The signatories are the parties whose authorization is required to create or archive contracts, in this case the user herself. The observers are the parties who are able to view the contract on the ledger. In this case all users that a particular user is following are able to see the user contract.

It's also important to distinguish between parties, users, and aliases in terms of naming:

Parties are unique across the entire Daml network. These must be allocated before you can use them to log in, and allocation results in a random-looking (but not actually random) string that identifies the party and is used in your Daml code. Parties are a builtin concept. On each participant node you can create users with human-readable user ids. Each user can be associated with one or more parties allocated on that participant node, and refers to that party only on that node. Users are a purely local concept, meaning you can never address a user on another node by user id, and you never work with users in your Daml code; party ids are always used for these purposes. Users are also a builtin concept. Lastly we have user aliases. These are not a builtin concept, they are defined by an *Alias template* (discussed below) within the specific model used in this guide. Aliases serve as a way to address parties on all nodes via a human readable name.

The social network users discussed in this guide are really a combination of all three of these concepts. Alice, Bob, and Charlie are all aliases that correspond to a single test user and a single party id each. As part of running `daml start`, the *init-script* specified in `daml.yaml` is executed. This points at the `Setup:setup` function which defines a *Daml Script* which creates 3 users *alice*, *bob* and *charlie* as well as a corresponding party for each they can act as. In addition to that, we also create a separate public party and allow the three users to read contracts for that party. This allows us to share the alias contracts with that public party and have them be visible to all 3 users.

Now let's see what the `signatory` and `observer` clauses mean in our app in more concrete terms. The user with the alias Alice can see another user, alias Bob, in the network only when Bob is following Alice (only if Alice is in the `following` list in his user contract). For this to be true, Bob must have previously started to follow Alice, as he is the sole signatory on his user contract. If not, Bob will be invisible to Alice.

This illustrates two concepts that are central to Daml: *authorization* and *privacy*. Authorization is about who can do what, and privacy is about who can see what. In Daml you must answer these questions upfront, as they are fundamental to the design of the application.

The next part of the Daml model is the operation to follow users, called a *choice* in Daml:

```
nonconsuming choice Follow: ContractId User with
  userToFollow: Party
  controller username
do
  assertMsg "You cannot follow yourself" (userToFollow /= username)
  assertMsg "You cannot follow the same user twice" (notElem userToFollow
    following)
  archive self
  create this with following = userToFollow :: following
```

Daml contracts are *immutable* (can not be changed in place), so the only way to update one is to archive it and create a new instance. That is what the `Follow` choice does: after checking some preconditions, it archives the current user contract and creates a new one with the new user to follow added to the list. Here is a quick explanation of the code:

The choice starts with the `nonconsuming choice` keyword followed by the choice name `Follow`.

The return type of a choice is defined next. In this case it is `ContractId User`.

After that we declare choice parameters with the `with` keyword. Here this is the user we want to start following.

The keyword `controller` defines the `Party` that is allowed to execute the choice. In this case, it is the `username` party associated with the `User` contract.

The `do` keyword marks the start of the choice body where its functionality will be written.

After passing some checks, the current contract is archived with `archive self`.

A new `User` contract with the new user we have started following is created (the new user is added to the `following` list).

More detailed information on choices can be found in [our docs](#).

Finally, the `User.daml` file contains the `Alias` template that manages the link between user ids and their aliases. The alias template sets the public party we created in the setup script as the observer of the contract. Because we allow all users to read contracts visible to the public party, this allows e.g., Alice to see Bob's `Alias` contract.

```
template Alias with
  username: Party
  alias: Text
  public: Party
where
  signatory username
  observer public

key (username, public) : (Party, Party)
maintainer key._1
```

(continues on next page)

(continued from previous page)

```

nonconsuming choice Change: ContractId Alias with
  newAlias: Text
  controller username
do
  archive self
  create this with alias = newAlias

```

Let's move on to how our Daml model is reflected and used on the UI side.

7.2 TypeScript Code Generation

The user interface for our app is written in [TypeScript](#). TypeScript is a variant of JavaScript that provides more support during development through its type system.

To build an application on top of Daml, we need a way to refer to our Daml templates and choices in TypeScript. We do this using a Daml to TypeScript code generation tool in the SDK.

To run code generation, we first need to compile the Daml model to an archive format (a `.dar` file). The `daml codegen js` command then takes this file as argument to produce a number of TypeScript packages in the output folder.

```

daml build
daml codegen js .daml/dist/create-daml-app-0.1.0.dar -o daml.js

```

Now we have a TypeScript interface (types and companion objects) to our Daml model, which we'll use in our UI code next.

7.3 The UI

On top of TypeScript, we use the UI framework [React](#). React helps us write modular UI components using a functional style - a component is rerendered whenever one of its inputs changes - with careful use of global state.

Let's see an example of a React component. All components are in the `ui/src/components` folder. You can navigate there within Visual Studio Code using the file explorer on the left sidebar. We'll first look at `App.tsx`, which is the entry point to our application.

```

const App: React.FC = () => {
  const [credentials, setCredentials] = React.useState<
    Credentials | undefined
  >();
  if (credentials) {
    const PublicPartyLedger: React.FC = ({ children }) => {
      const publicToken = usePublicToken();
      const publicParty = usePublicParty();
      if (publicToken && publicParty) {
        return (
          <publicContext.DamlLedger
            token={publicToken.token}
            party={publicParty}>

```

(continues on next page)

(continued from previous page)

```

        {children}
      </publicContext.DamlLedger>
    );
  } else {
    return <h1>Loading ...</h1>;
  }
};
const Wrap: React.FC = ({ children }) =>
  isRunningOnHub() ? (
    <DamlHub token={credentials.token}>
      <PublicPartyLedger>{children}</PublicPartyLedger>
    </DamlHub>
  ) : (
    <div>{children}</div>
  );
return (
  <Wrap>
    <userContext.DamlLedger
      token={credentials.token}
      party={credentials.party}
      user={credentials.user}>
      <MainScreen
        getPublicParty={credentials.getPublicParty}
        onLogout={() => {
          if (authConfig.provider === "daml-hub") {
            damlHubLogout();
          }
          setCredentials(undefined);
        }}
      />
    </userContext.DamlLedger>
  </Wrap>
);
} else {
  return <LoginScreen onLogin={setCredentials} />;
}
};

```

An important tool in the design of our components is a React feature called [Hooks](#). Hooks allow you to share and update state across components, avoiding the need to thread it through manually. We take advantage of hooks to share ledger state across components. Custom [Daml React hooks](#) query the ledger for contracts, create new contracts, and exercise choices. This is the library you will use most often when interacting with the ledger¹.

The `useState` hook (not specific to Daml) here keeps track of the user's credentials. If they are not set, we render the `LoginScreen` with a callback to `setCredentials`. If they are set, we render the `MainScreen` of the app. This is wrapped in the `DamlLedger` component, a [React context](#) with a handle to the ledger.

Let's move on to more advanced uses of our Daml React library. The `MainScreen` is a simple frame around the `MainView` component, which houses the main functionality of our app. It uses Daml React hooks to query and update ledger state.

¹ Behind the scenes the Daml React hooks library uses the [Daml Ledger TypeScript library](#) to communicate with a ledger implementation via the [HTTP JSON API](#).

```
const MainView: React.FC = () => {
  const username = useContext.useParty();
  const myUserResult = useContext.useStreamFetchByKeys(User.User, () => [
    username, [username]
  ]);
  const aliases = publicContext.useStreamQueries(User.Alias, () => [], []);
  const myUser = myUserResult.contracts[0]?.payload;
  const allUsers = useContext.useStreamQueries(User.User).contracts;
}
```

The `useParty` hook returns the current user as stored in the `DamlLedger` context. A more interesting example is the `allUsers` line. This uses the `useStreamQueries` hook to get all `User` contracts on the ledger. (`User.User` here is an object generated by `daml codegen js` - it stores metadata of the `User` template defined in `User.daml`.) Note however that this query preserves privacy: only users that follow the current user have their contracts revealed. This behaviour is due to the observers on the `User` contract being exactly in the list of users that the current user is following.

A final point on this is the *streaming* aspect of the query. Results are updated as they come in - there is no need for periodic or manual reloading to see updates.

Another example, showing how to update ledger state, is how we exercise the `Follow` choice of the `User` template.

```
const ledger = useContext.useLedger();

const follow = async (userToFollow: Party): Promise<boolean> => {
  try {
    await ledger.exerciseByKey(User.User.Follow, username, {userToFollow});
    return true;
  } catch (error) {
    alert(`Unknown error:\n${JSON.stringify(error)}`);
    return false;
  }
}
```

The `useLedger` hook returns an object with methods for exercising choices. The core of the `follow` function here is the call to `ledger.exerciseByKey`. The key in this case is the username of the current user, used to look up the corresponding `User` contract. The wrapper function `follow` is then passed to the subcomponents of `MainView`. For example, `follow` is passed to the `UserList` component as an argument (a `prop` in React terms). This is triggered when you click the icon next to a user's name in the `Network` panel.

```
<UserList
  users={followers}
  partyToAlias={partyToAlias}
  onFollow={follow}
/>
```

This should give you a taste of how the UI works alongside a Daml ledger. You'll see this more as you develop [your first feature](#) for our social network.

Chapter 8

Your First Feature

To get a better idea of how to develop Daml applications, let's try implementing a new feature for our social network app.

At the moment, our app lets us follow users in the network, but we have no way to communicate with them. Let's fix that by adding a *direct messaging* feature. This should let users that follow each other send messages to each other, respecting *authorization* and *privacy*. This means:

You cannot send a message to someone unless they have given you the authority by following you back.

You cannot see a message unless you sent it or it was sent to you.

Daml lets us implement these guarantees in a direct and intuitive way.

Creating a feature involves three steps:

1. Adding the necessary changes to the Daml model
2. Making the corresponding changes in the UI
3. Running the app with the new feature

As usual, we must start with the Daml model and base our UI changes on top of that.

8.1 Daml Changes

The Daml code defines the *data* and *workflow* of the application; you can read about this in more detail in the [architecture](#) section. The workflow refers to the interactions between parties that are permitted by the system. In the context of a messaging feature, these are essentially the authorization and privacy concerns listed above.

For the authorization part, we take the following approach: a user Bob can message another user Alice when Alice starts following Bob back. When Alice starts following Bob back, she gives permission or *authority* to Bob to send her a message.

To implement this workflow, let's start by adding the new *data* for messages. Navigate to the `daml/User.daml` file and copy the following `Message` template to the bottom. Indentation is important: it should be at the top level like the original `User` template.

```
template Message with
  sender: Party
  receiver: Party
```

(continues on next page)

(continued from previous page)

```

content: Text
where
  signatory sender, receiver

```

This template is very simple: it contains the data for a message and no choices. The interesting part is the `signatory` clause: both the `sender` and `receiver` are signatories on the template. This enforces that creation and archival of `Message` contracts must be authorized by both parties.

Now we can add messaging into the workflow by adding a new choice to the `User` template. Copy the following choice to the `User` template after the `Follow` choice. The indentation for the `SendMessage` choice must match the one of `Follow`. Make sure you save the file after copying the code.

```

nonconsuming choice SendMessage: ContractId Message with
  sender: Party
  content: Text
  controller sender
do
  assertMsg "Designated user must follow you back to send a message" (elem
    sender following)
  create Message with sender, receiver = username, content

```

As with the `Follow` choice, there are a few aspects to note here.

By convention, the choice returns the `ContractId` of the resulting `Message` contract.

The parameters to the choice are the `sender` and `content` of this message; the `receiver` is the party named on this `User` contract.

The `controller` clause states that it is the `sender` who can exercise the choice.

The body of the choice first ensures that the `sender` is a user that the `receiver` is following and then creates the `Message` contract with the `receiver` being the signatory of the `User` contract.

This completes the workflow for messaging in our app.

Navigate to the terminal window where the `daml start` process is running and press ‘r’. This will

Compile our Daml code into a *DAR file containing the new feature*

Update the JavaScript library under `ui/daml.js` to connect the UI with your Daml code

Upload the *new DAR file* to the sandbox

As mentioned previously, Daml Sandbox uses an in-memory store, which means it loses its state – which here includes all user data and follower relationships – when stopped or restarted.

Now let’s integrate the new functionality into the UI.

8.2 Messaging UI

The UI for messaging consists of a new `Messages` panel in addition to the `Follow` and `Network` panel. This new panel has two parts:

1. A list of messages you’ve received with their senders.
2. A form with a dropdown menu for follower selection and a text field for composing the message.

We implement each part as a React component, named `MessageList` and `MessageEdit` respectively. Let’s start with the simpler `MessageList`.

8.2.1 MessageList Component

The goal of the `MessageList` component is to query all `Message` contracts where the receiver is the current user, and display their contents and senders in a list. The entire component is shown below. Copy this into a new `MessageList.tsx` file in `ui/src/components` and save it.

```
import React from 'react'
import { List, ListItem } from 'semantic-ui-react';
import { User } from '@daml.js/create-daml-app';
import { useContext } from './App';

type Props = {
  partyToAlias: Map<string, string>
}

/**
 * React component displaying the list of messages for the current user.
 */
const MessageList: React.FC<Props> = ({partyToAlias}) => {
  const messagesResult = useContext(User.Message);

  return (
    <List relaxed>
      {messagesResult.contracts.map(message => {
        const {sender, receiver, content} = message.payload;
        return (
          <ListItem
            className='test-select-message-item'
            key={message.contractId}>
            <strong>{partyToAlias.get(sender) ?? sender} &rarr; {partyToAlias.
get(receiver) ?? receiver};</strong> {content}
          </ListItem>
        );
      })}
    </List>
  );
};

export default MessageList;
```

In the component body, `messagesResult` gets the stream of all `Message` contracts visible to the current user. The streaming aspect means that we don't need to reload the page when new messages come in. For each contract in the stream, we destructure the `payload` (the data as opposed to metadata like the contract ID) into the `{sender, receiver, content}` object pattern. Then we construct a `ListItem` UI element with the details of the message.

An important point about privacy: no matter how we write our `Message` query in the UI code, it is impossible to break the privacy rules given by the Daml model. That is, it is impossible to see a `Message` contract of which you are not the `sender` or the `receiver` (the only parties that can observe the contract). This is a major benefit of writing apps on Daml: the burden of ensuring privacy and authorization is confined to the Daml model.

8.2.2 MessageEdit Component

Next we need the `MessageEdit` component to compose and send messages to our followers. Again we show the entire component here; copy this into a new `MessageEdit.tsx` file in `ui/src/components` and save it.

```
import React from 'react'
import { Form, Button } from 'semantic-ui-react';
import { Party } from '@daml/types';
import { User } from '@daml.js/create-daml-app';
import { useContext } from './App';

type Props = {
  followers: Party[];
  partyToAlias: Map<string, string>;
}

/**
 * React component to edit a message to send to a follower.
 */
const MessageEdit: React.FC<Props> = ({followers, partyToAlias}) => {
  const sender = useContext().useParty();
  const [receiver, setReceiver] = React.useState<string | undefined>();
  const [content, setContent] = React.useState('');
  const [isSubmitting, setIsSubmitting] = React.useState(false);
  const ledger = useContext().useLedger();

  const submitMessage = async (event: React.FormEvent) => {
    try {
      event.preventDefault();
      if (receiver === undefined) {
        return;
      }
      setIsSubmitting(true);
      await ledger.exerciseByKey(User.User.SendMessage, receiver, {sender,
↵content});
      setContent('');
    } catch (error) {
      alert(`Error sending message:\n${JSON.stringify(error)}`);
    } finally {
      setIsSubmitting(false);
    }
  };

  return (
    <Form onSubmit={submitMessage}>
      <Form.Select
        fluid
        search
        className='test-select-message-receiver'
        placeholder={receiver ? partyToAlias.get(receiver) ?? receiver : "Select
↵a follower"}
        value={receiver}
        options={followers.map(follower => ({ key: follower, text: partyToAlias.
↵get(follower) ?? follower, value: follower })))
        onChange={(event, data) => setReceiver(data.value?.toString())}
      />

```

(continues on next page)

(continued from previous page)

```

<Form.Input
  className='test-select-message-content'
  placeholder="Write a message"
  value={content}
  onChange={event => setContent(event.currentTarget.value)}
/>
<Button
  fluid
  className='test-select-message-send-button'
  type="submit"
  disabled={isSubmitting || receiver === undefined || content === ""}
  loading={isSubmitting}
  content="Send"
/>
</Form>
);
};

export default MessageEdit;

```

You will first notice a `Props` type near the top of the file with a single `followers` field. A *prop* in React is an input to a component; in this case a list of users from which to select the message receiver. The prop will be passed down from the `MainView` component, reusing the work required to query users from the ledger. You can see this `followers` field bound at the start of the `MessageEdit` component.

We use the React `useState` hook to get and set the current choices of message receiver and content. The Daml-specific `useLedger` hook gives us an object we can use to perform ledger operations. The call to `ledger.exerciseByKey` in `submitMessage` looks up the `User` contract with the receiver's username and exercises the `SendMessage` choice with the appropriate arguments. If the choice fails, the `catch` block reports the error in a dialog box. Additionally, `submitMessage` sets the `isSubmitting` state so that the `Send` button is disabled while the request is processed. The result of a successful call to `submitMessage` is a new `Message` contract created on the ledger.

The return value of this component is the React `Form` element. This contains a dropdown menu to select a receiver from the `followers`, a text field for the message content, and a `Send` button which triggers `submitMessage`.

Note how *authorization* is enforced here. Due to the logic of the `SendMessage` choice, it is impossible to send a message to a user who is not following us (even if you could somehow access their `User` contract). The assertion that `elem.sender.following` in `SendMessage` ensures this: no mistake or malice by the UI programmer could breach this.

8.2.3 MainView Component

Finally we can see these components come together in the `MainView` component. We want to add a new panel to house our messaging UI. Open the `ui/src/components/MainView.tsx` file and start by adding imports for the two new components.

```

import MessageEdit from './MessageEdit';
import MessageList from './MessageList';

```

Next, find where the `Network Segment` closes, towards the end of the component. This is where we'll add a new `Segment` for `Messages`. Make sure you save the file after copying over the code.

```

<Segment>
  <Header as='h2'>
    <Icon name='pencil square' />
    <Header.Content>
      Messages
      <Header.Subheader>Send a message to a follower</Header.
↪Subheader>
    </Header.Content>
  </Header>
  <MessageEdit
    followers={followers.map(follower => follower.username)}
    partyToAlias={partyToAlias}
  />
  <Divider />
  <MessageList partyToAlias={partyToAlias}/>
</Segment>

```

Following the formatting of the previous panels, we include the new messaging components: `MessageEdit` supplied with the usernames of all visible parties as props, and `MessageList` to display all messages.

That is all for the implementation! Let's give the new functionality a spin.

8.3 Run the Updated UI

If you have the frontend UI up and running you're all set. If you don't have the UI running, open a new terminal window and navigate to the `create-daml-app/ui` folder, then run the `npm start` command to start the UI.

You should see the same login page as before at <http://localhost:3000>.

Once you've logged in, you'll see a familiar UI but with our new *Messages* panel at the bottom!

Go ahead and follow more users, and log in as some of those users in separate browser windows to follow yourself back. Then click on the dropdown menu in the *Messages* panel to see a choice of followers to message!

Daml

You are logged in as Bob.

Welcome, Bob!

 **Bob**

Users I'm following

Username to follow

Follow

 **The Network**

My followers and users they are following

 **Messages**

Send a message to a follower

Select a follower

Write a message

Send

 **Messages**

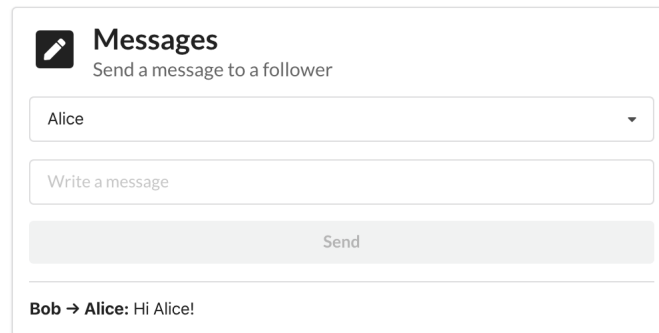

Send a message to a follower

Alice

Alice

Send

Send some messages between users and make sure you can see each one from the other side. Notice that each new message appears in the UI as soon as it is sent (due to the *streaming* React hooks).

The screenshot shows a web interface for sending messages. At the top, there's a header with a pencil icon and the title 'Messages', followed by the subtitle 'Send a message to a follower'. Below this is a dropdown menu with 'Alice' selected. Underneath is a text input field with the placeholder 'Write a message'. A 'Send' button is positioned below the input field. At the bottom, a message history shows 'Bob → Alice: Hi Alice!'.

Tip: You completed the second part of the Getting Started Guide! [Join our forum](#) and share a screenshot of your accomplishment to [get your second of 3 badges](#)! Get the third badge by [deploying to Daml Hub](#).

8.4 Next Steps

We've gone through the process of setting up a full-stack Daml app and implementing a useful feature end to end. As the next step we encourage you to really dig into the fundamentals of Daml and understand its core concepts such as parties, signatories, observers, and controllers. You can do that either by [going through our docs](#) or by taking an [online course](#).

After you've got a good grip on these concepts learn [how to conduct end-to-end testing of your app](#).

Chapter 9

Test Your App

When developing a UI for your Daml application, you will want to test that user flows work from end to end. This means that actions performed in the web UI trigger updates to the ledger and give the desired results on the page. In this section we show how you can do such testing automatically in TypeScript (equally JavaScript). This will allow you to iterate on your app faster and with more confidence!

There are two tools that we chose to write end to end tests for our app. Of course there are more to choose from, but this is one combination that works.

[Jest](#) is a general-purpose testing framework for JavaScript that's well integrated with both TypeScript and React. Jest helps you structure your tests and express expectations of the app's behaviour.

[Puppeteer](#) is a library for controlling a Chrome browser from JavaScript/TypeScript. Puppeteer allows you to simulate interactions with the app in place of a real user.

To install Puppeteer and some other testing utilities we are going to use, run the following command in the `ui` directory:

```
npm i --save-dev puppeteer@~10.0.0 wait-on@~6.0.1 @types/jest@~29.2.3 @types/  
node@~18.11.9 @types/puppeteer@~7.0.4 @types/wait-on@~5.3.1
```

You may need to run `npm install` again afterwards.

Because these things are easier to describe with concrete examples, this section will show how to set up end-to-end tests for the application you would end with at the end of the [Your First Feature](#) section.

9.1 Set Up the Tests

Let's see how to use these tools to write some tests for our social network app. You can see the full suite in section [The Full Test Suite](#) at the bottom of this page. To run this test suite, create a new file `ui/src/index.test.ts`, copy the code in this section into that file and run the following command in the `ui` folder:

```
npm test
```

The actual tests are the clauses beginning with `test`. You can scroll down to the important ones with the following descriptions (the first argument to each `test`):

'log in as a new user, log out and log back in'
 'log in as three different users and start following each other'
 'error when following self'
 'error when adding a user that you are already following'

Before this, we need to set up the environment in which the tests run. At the top of the file we have some global state that we use throughout. Specifically, we have child processes for the `daml start` and `npm start` commands, which run for the duration of our tests. We also have a single Puppeteer browser that we share among tests, opening new browser pages for each one.

The `beforeAll()` section is a function run once before any of the tests run. We use it to spawn the `daml start` and `npm start` processes and launch the browser. On the other hand the `afterAll()` section is used to shut down these processes and close the browser. This step is important to prevent child processes persisting in the background after our program has finished.

9.2 Example: Log In and Out

Now let's get to a test! The idea is to control the browser in the same way we would expect a user to in each scenario we want to test. This means we use Puppeteer to type text into input forms, click buttons and search for particular elements on the page. In order to find those elements, we do need to make some adjustments in our React components, which we'll show later. Let's start at a higher level with a test.

```
test("log in as a new user, log out and log back in", async () => {
  const [user, party] = await getParty();

  // Log in as a new user.
  const page = await newUiPage();
  await login(page, user);

  // Check that the ledger contains the new User contract.
  const token = insecure.makeToken(user);
  const ledger = new Ledger({ token });
  const users = await ledger.query(User.User);
  expect(users).toHaveLength(1);
  expect(users[0].payload.username).toEqual(party);

  // Log out and in again as the same user.
  await logout(page);
  await login(page, user);

  // Check we have the same one user.
  const usersFinal = await ledger.query(User.User);
  expect(usersFinal).toHaveLength(1);
  expect(usersFinal[0].payload.username).toEqual(party);

  await page.close();
}, 40_000);
```

We'll walk through this step by step.

The test syntax is provided by Jest to indicate a new test running the function given as an argument (along with a description and time limit).

`getParty()` gives us a new party name. Right now it is just a string unique to this set of tests, but in the future we will use the Party Management Service to allocate parties.

`newUiPage()` is a helper function that uses the Puppeteer browser to open a new page (we use one page per party in these tests), navigate to the app URL and return a `Page` object.

Next we `login()` using the new page and party name. This should take the user to the main screen. We'll show how the `login()` function does this shortly.

We use the `@daml/ledger` library to check the ledger state. In this case, we want to ensure there is a single `User` contract created for the new party. Hence we create a new connection to the Ledger, `query()` it and state what we expect of the result. When we run the tests, Jest will check these expectations and report any failures for us to fix.

The test also simulates the new user logging out and then logging back in. We again check the state of the ledger and see that it's the same as before.

Finally we must `close()` the browser page, which was opened in `newUiPage()`, to avoid run-away Puppeteer processes after the tests finish.

You will likely use `test`, `getParty()`, `newUiPage()` and `Browser.close()` for all your tests. In this case we use the `@daml/ledger` library to inspect the state of the ledger, but usually we just check the contents of the web page match our expectations.

9.3 Accessing UI Elements

We showed how to write a simple test at a high level, but haven't shown how to make individual actions in the app using Puppeteer. This was hidden in the `login()` and `logout()` functions. Let's see how `login()` is implemented.

```
// Log in using a party name and wait for the main screen to load.
const login = async (page: Page, partyName: string) => {
  const usernameInput = await page.waitForSelector(
    ".test-select-username-field",
  );
  if (usernameInput) {
    await usernameInput.click();
    await usernameInput.type(partyName);
    await page.click(".test-select-login-button");
    await page.waitForSelector(".test-select-main-menu");
  }
};
```

We first wait to receive a handle to the username input element. This is important to ensure the page and relevant elements are loaded by the time we try to act on them. We then use the element handle to click into the input and type the party name. Next we click the login button (this time assuming the button has loaded along with the rest of the page). Finally, we wait until we find we've reached the menu on the main page.

The strings used to find UI elements, e.g. `'.test-select-username-field'` and `'.test-select-login-button'`, are [CSS Selectors](#). You may have seen them before in CSS styling of web pages. In this case we use *class selectors*, which look for CSS classes we've given to elements in our React components.

This means we must manually add classes to the components we want to test. For example, here is a snippet of the `LoginScreen` React component with classes added to the `Form` elements.

```
<Form.Input
  fluid
  placeholder="Username"
```

(continues on next page)

(continued from previous page)

```

    value={username}
    className="test-select-username-field"
    onChange={(e, { value }) => setUsername(value?.toString() ?? "")}
  />
  <Button
    primary
    fluid
    className="test-select-login-button"
    onClick={handleLogin}>
    Log in
  </Button>

```

You can see the `className` attributes in the `Input` and `Button`, which we select in the `login()` function. Note that you can use other features of an element in your selector, such as its type and attributes. We've only used class selectors in these tests.

9.4 Writing CSS Selectors

When writing CSS selectors for your tests, you will likely need to check the structure of the rendered HTML in your app by running it manually and inspecting elements using your browser's developer tools. For example, the image below is from inspecting the username field using the developer tools in Google Chrome.

There is a subtlety to explain here due to the [Semantic UI](#) framework we use for our app. Semantic UI provides a convenient set of UI elements which get translated to HTML. In the example of the username field above, the original Semantic UI `Input` is translated to nested `div` nodes with the `input` inside. You can see this highlighted on the right side of the screenshot. While harmless in this case, in general you may need to inspect the HTML translation of UI elements and write your CSS selectors accordingly.

Chapter 10

Important Considerations When Building Applications With Daml

10.1 Overall Considerations

Because Daml provides a unique and innovative solution to the problem of multi-party applications, some of the common architectural approaches used in existing solutions do not apply when working with Daml. You must understand Daml's architecture and principles and design your application and deployment approaches accordingly.

Canton is fast and highly scalable, but it performs differently than traditional databases, particularly those that follow a monolithic architecture. Transactions are processed in fractions of a second – quite fast for a distributed ledger (the blockchains used in cryptocurrencies like Bitcoin or Ethereum take many minutes to complete transactions) but slower than most traditional databases due to its distributed nature. Application design must take this into account.

Each component of Daml can be scaled, including running multiple sync domains, multiple participant nodes, and multiple parties. Integration components, e.g. HTTP JSON API Service and Trigger Service ([deprecated](#)), also scale. Some components require that data is sharded in order to scale.

10.2 Developer Considerations

When programming within a distributed system like Daml, the developer must view every action of the system as an asynchronous operation; contention is natural and expected. This contention can stifle the performance of applications if not handled properly. The aim is to reduce contention and handle it gracefully, not to eliminate it at all costs. If contention only occurs rarely, it may be cheaper in terms of both performance and complexity to let the occasional allocation fail and retry it than to implement sharding or other complex processes.

Application design must understand the sources of contention; this allows you to use different techniques to manage it and improve performance by increasing throughput and decreasing latency. These techniques include:

- Bundling or batching business logic to increase business transaction throughput - the marginal cost of extra business logic within a transaction is often small, so bundling or batching business logic cleverly can allow for throughput an order of magnitude higher.

Maximizing parallelism with techniques like sharding, ensuring there is no contention between shards.

When designing Daml applications:

- Understand where contention occurs

- Split contracts across natural lines to reduce single high contention contracts (e.g., don't represent asset holdings for all owners and types as a dictionary on a single contract, but as individual contracts)

- Partition contracts along natural lines and touch as few partitions as possible in each transaction (e.g., partition all asset positions into total asset positions, and then only touch one total asset position per transaction)

- Use contention-free representations where possible

For more information, see the section on [Avoiding Contention](#).

The Daml language follows functional programming principles. To build safe, secure smart contracts with Daml, we recommend that the developers embrace functional programming.

The Daml SDK contains tools and libraries that simplify multi-party application development, including defining the application's schema and implementing off-ledger code that leverages the Canton APIs.

10.3 Operational Considerations

Most components of Daml store state, so deployment techniques that follow stateless practices can be problematic within Daml. Achieving high availability and scalability requires clear understanding of the purpose of each component within the Daml solution. While all components in Daml scale horizontally, stateful components (e.g. participant nodes) scale horizontally via sharding.

The diagram below shows the components often used in a Daml deployment. High availability is achieved via either active-active (HTTP JSON API Service, sequencer) or active-passive (participant node, mediator) clustering. Node scaling is achieved via horizontal scaling with participant nodes requiring sharding across participants.

10.4 Next Steps

Go to [An Introduction to Daml](#) to begin learning how to write smart contracts with Daml.

Chapter 11

Write Smart Contracts with Daml

11.1 An Introduction to Daml

Daml is a smart contract language designed to build composable applications on an abstract [Daml Ledger Model Concepts](#).

In this introduction, you will learn about the structure of a Daml Ledger, and how to write Daml applications that run on any Daml Ledger implementation, by building an asset-holding and -trading application. You will gain an overview over most important language features, how they relate to the [Daml Ledger Model Concepts](#) and how to use Daml's developer tools to write, test, compile, package and ship your application.

This introduction is structured such that each section presents a new self-contained application with more functionality than that from the previous section. You can find the Daml code for each section [here](#) or download them using the Daml assistant. For example, to load the sources for section 1 into a folder called `intro1`, run `daml new intro1 --template daml-intro-1`.

Prerequisites:

You have installed the [Daml SDK](#)

Next: [Basic Contracts](#).

11.2 Basic Contracts

To begin with, you're going to write a very small Daml template, which represents a self-issued, non-transferable token. Because it's a minimal template, it isn't actually useful on its own - you'll make it more useful later - but it's enough that it can show you the most basic concepts:

- Transactions
- Daml Modules and Files
- Templates
- Contracts
- Signatories

Hint: Remember that you can load all the code for this section into a folder `intro1` by running `daml new intro1 --template daml-intro-1`

11.2.1 Daml Ledger Basics

Like most structures called ledgers, a Daml Ledger is just a list of *commits*. When we say *commit*, we mean the final result of when a party successfully *submits* a *transaction* to the ledger.

Transaction is a concept we'll cover in more detail through this introduction. The most basic examples are the creation and archival of a *contract*.

A contract is *active* from the point where there is a committed transaction that creates it, up to the point where there is a committed transaction that *archives* it.

Individual contracts are *immutable* in the sense that an active contract can not be changed. You can only change the *active contract* set by creating a new contract, or archiving an old one.

Daml specifies what transactions are legal on a Daml Ledger. The rules the Daml code specifies are collectively called a *Daml model* or *contract model*.

11.2.2 Daml Modules and Files

Each `.daml` file defines a *Daml Module* at the top:

```
module Token where
```

Code comments in Daml are introduced with `--`:

```
-- A Daml file defines a module.
module Token where
```

11.2.3 Templates

A `template` defines a type of contract that can be created, and who has the right to do so. *Contracts* are instances of *templates*.

Listing 1: A simple template

```
template Token
  with
    owner : Party
  where
    signatory owner
```

You declare a template starting with the `template` keyword, which takes a name as an argument.

Daml is whitespace-aware and uses layout to structure *blocks*. Everything that's below the first line is indented, and thus part of the template's body.

Contracts contain data, referred to as the *create arguments* or simply *arguments*. The `with` block defines the data type of the create arguments by listing field names and their types. The single colon `:` means *of type*, so you can read this as `template Token` with a field `owner` of type `Party`.

`Token` contracts have a single field `owner` of type `Party`. The fields declared in a template's `with` block are in scope in the rest of the template body, which is contained in a `where` block.

11.2.4 Signatories

The `signatory` keyword specifies the *signatories* of a contract. These are the parties whose authority is required to create the contract or archive it – just like a real contract. Every contract must have at least one signatory.

Furthermore, Daml ledgers *guarantee* that parties see all transactions where their authority is used. This means that signatories of a contract are guaranteed to see the creation and archival of that contract.

11.2.5 Next Up

In [Test Templates Using Daml Script](#), you'll learn about how to try out the `Token` contract template in Daml's inbuilt Daml Script testing language.

11.3 Test Templates Using Daml Script

In this section we test the `Token` model from [Basic Contracts](#) using the [Daml Script](#) integration in [Daml Studio](#). This includes:

- Script basics
- Running scripts
- Creating contracts
- Testing for failure
- Archiving contracts
- Viewing the ledger and ledger history

Hint: Remember that you can load all the code for this section into a folder called `intro2` by running `daml new intro2 --template daml-intro-2`

11.3.1 Script Basics

A `Script` is like a recipe for a test, letting you create a scenario where different parties submit a series of transactions to check that your templates behave as you expect. You can also script some external information like party identities and ledger time.

Below is a basic script that creates a `Token` for a party called `Alice` :

```
token_test_1 = script do
  alice <- allocateParty "Alice"
  submit alice do
    createCmd Token with owner = alice
```

You declare a `Script` as a top-level variable and introduce it using `script do`. `do` always starts a block, so the rest of the script is indented.

Before you can create any `Token` contracts, you need some parties on the test ledger. The above script uses the function `allocateParty` to put a party called `Alice` in a variable `alice`. There are two things of note there:

Use of `<-` instead of `=`.

The reason for this is that `allocateParty` is an `Action` that can only be performed once the `Script` is run in the context of a ledger. `<-` means “run the action and bind the result”. It can only be run in that context because, depending on the ledger state, `allocateParty` gives you back a party with the name you specified or appends a suffix to that name if such a party has already been allocated. You can read more about `Actions` and `do` blocks in [Add Constraints to a Contract](#).

If that doesn't quite make sense yet, for the time being you can think of this arrow as extracting the right-hand-side value from the ledger and storing it into the variable on the left.

The argument `"Alice"` to `allocateParty` does not have to be enclosed in brackets. Functions in Daml are called using the syntax `fn arg1 arg2 arg3`.

With a variable `alice` of type `Party` in hand, you can submit your first transaction using the `submit` function. `submit` takes two arguments: the `Party` and the `Commands`.

Just like `Script` is a recipe for a test, `Commands` is a recipe for a transaction. `createCmd Token with owner = alice` is a `Commands`, which translates to a list of commands to be submitted to the ledger. These commands create a transaction which in turns creates a `Token` with owner `Alice`.

You'll learn all about the syntax `Token with owner = alice` in [Data Types](#).

You could write this as `submit alice (createCmd Token with owner = alice)`, but as with scripts, you can assemble commands using `do` blocks. A `do` block always takes the value of the last statement within it so the syntax shown in the commands above gives the same result, whilst being easier to read. Note, however, that the commands submitted as part of a transaction are not allowed to depend on each other.

11.3.2 Run the Scripts

There are a few ways to run Daml Scripts:

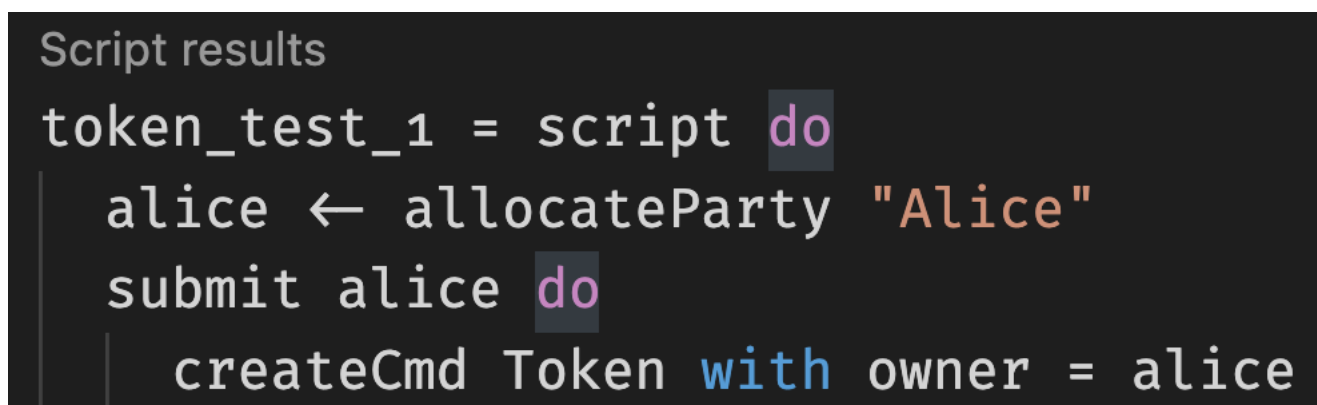

In Daml Studio against a test ledger, providing visualizations of the resulting ledger.

Using the command line `daml test` also against a test ledger, useful for continuous integration.

Against a real ledger. See the documentation for [Daml Script](#) for more information.

Interactively using [Daml REPL \(Deprecated\)](#).

In Daml Studio, you should see the text `Script results` just above the line `token_test_1 = do`. Click on that text to display the outcome of the script.

```
Script results
token_test_1 = script do
  alice ← allocateParty "Alice"
  submit alice do
    createCmd Token with owner = alice
```

This opens the script view in a separate column in VS Code. The default view is a tabular representation of the final state of the ledger:

Script: token_test_1
×

Show transaction view
☐ Show archived
☐ Show detailed disclosure

Token_Test:Token

id	status	owner	Alice
#0:0	active	'Alice'	X

What this display means:

The big title reading `Token_Test:Token` identifies the type of contract that's listed below. `Token_Test` is the module name, `Token` is the template name.

The first column shows the ID of the contract. This will be explained later.

The second column shows the status of the contract, either `active` or `archived`.

The next section of columns show the contract arguments, with one column per field. As expected, here there is one field and thus one column: the field `owner` is `'Alice'`. The single quotation marks indicate that `Alice` is a party.

The remaining columns, labelled vertically, show which parties know about which contracts. In this simple script, the sole party `Alice` knows about the contract she created.

To run the same test from the command line, save your module in a file `Token_Test.daml` and run `daml test --files Token_Test.daml`. If your file contains more than one script, this runs all of them.

11.3.3 Test for Failure

In [Basic Contracts](#) you learned that creating a `Token` requires the authority of its owner. In other words, it should not be possible for Alice to create a token for another party, e.g. Bob, or vice versa. A reasonable attempt to test that would be:

```
failing_test_1 = do
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"
  submit alice do
    createCmd Token with owner = bob
  submit bob do
    createCmd Token with owner = alice
```

However, if you open the script view for that script, you see the following message:

The script failed, as expected, but scripts abort at the first failure. This means that it only tested that Alice cannot create a token for Bob; the second `submit` statement was never reached.

To test for failing submits and keep the script running thereafter, or fail if the submission succeeds, you can use the `submitMustFail` function:

```
Script execution failed on commit at Token\_Test:64:3:
  0: create of Token\_Test:Token at DA.Internal.Template.Functions:229:3
    failed due to a missing authorization from 'Bob'
```

```
Ledger time: 1970-01-01T00:00:00Z
```

```
Partial transaction:
```

```
Sub-transactions:
```

```
  0
    ↳ 'Bob' creates Token\_Test:Token
      with
        owner = 'Bob'
```

```
token_test_2 = do
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"

  submitMustFail alice do
    createCmd Token with owner = bob
  submitMustFail bob do
    createCmd Token with owner = alice

  submit alice do
    createCmd Token with owner = alice
  submit bob do
    createCmd Token with owner = bob
```

submitMustFail never has an impact on the ledger, so the resulting tabular script view only shows the two tokens resulting from the successful submit statements. Note the new column for Bob as well as the visibilities. Alice and Bob cannot see each others' tokens.

Script: token_test_2 ×

Show transaction view

Show archived

Show detailed

disclosure

Token_Test:Token

id	status	owner	Alice	Bob
#2:0	active	'Alice'	X	-
#3:0	active	'Bob'	-	X

11.3.4 Archive Contracts

Archiving contracts is the counterpart to creating contracts. Contracts are immutable, so whenever you want to update one (loosely: change its state) you must archive the current contract residing on the ledger and create a new one.

To archive a contract, use `archiveCmd` instead of `createCmd`. Whereas `createCmd` takes an instance of a template, `archiveCmd` takes a reference to a created contract. Archiving requires authorization from controllers.

Contracts are also archived whenever a [consuming choice](#) is exercised.

Important: Archive choices are present on all templates and cannot be removed.

References to contracts have the type `ContractId a`, where `a` is a type parameter representing the template type of the contract that the id refers to. For example, a reference to a `Token` would be a `ContractId Token`.

To `archiveCmd` the token Alice has created, you need the contract id. Retrieve the contract id from the ledger with the `<-` notation. How this works is discussed in [Add Constraints to a Contract](#).

This script first checks that Bob cannot archive Alice's token. Then Alice successfully archives it:

```
token_test_3 = do
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"

  alice_token <- submit alice do
    createCmd Token with owner = alice

  submitMustFail bob do
    archiveCmd alice_token

  submit alice do
    archiveCmd alice_token
```

11.3.5 View the Ledger and Ledger History

Once you archive the contract the resulting script view is empty; there are no contracts left on the ledger. If you want to see the history of the ledger, e.g. to see how you got to that state, tick the `Show archived` box at the top of the ledger view:

You can see that there was a `Token` contract, which is now archived, indicated both by the `archived` value in the `status` column as well as by a strikethrough.

Click on the adjacent `Show transaction view` button to see the entire transaction graph:

In the Daml Studio script runner, committed transactions are numbered sequentially. In the image above, the lines starting with `TX` indicate that there are three committed transactions, with ids #0, #1, and #2. These correspond to the three `submit` and `submitMustFail` statements in the script.

Transaction #0 has one *sub-transaction* #0:0, which the arrow indicates is a `create` of a `Token`. Identifiers `#X:Y` mean *commit X, sub-transaction Y*. All transactions have this format in the script runner. However, this format is a testing feature. In general, you should consider Transaction and Contract IDs to be opaque.

Script: token_test_3 X

Show transaction view

Show archived

Show detailed disclosure

Token_Test:Token

id	status	owner	Alice
#0:0	archived	'Alice'	X

Script: token_test_3 X

Show table view

Transactions:

TX 0 1970-01-01T00:00:00Z ([Token_Test:92:18](#))
 #0:0

consumed by: [#2:0](#)
 referenced by [#2:0](#)
 disclosed to (since): 'Alice' (0)
 → 'Alice' creates [Token_Test:Token](#)
 with
 owner = 'Alice'

TX 1 1970-01-01T00:00:00Z
 mustFailAt actAs: {'Bob'} readAs: {} ([Token_Test:95:3](#))

TX 2 1970-01-01T00:00:00Z ([Token_Test:98:3](#))
 #2:0

disclosed to (since): 'Alice' (2)
 → 'Alice' exercises Archive on [#0:0](#) ([Token_Test:Token](#))

Active contracts:

Return value: {}

The lines above and below `create Token_Test:Token` give additional information:

`consumed by: #2:0` tells you that the contract is archived in sub-transaction 0 of commit 2.

`referenced by #2:0` tells you that the contract was used in other transactions, and lists their IDs.

`disclosed to (since): 'Alice' (#0)` tells you who knows about the contract. The fact that 'Alice' appears in the list is equivalent to an `x` in the tabular view. The `(#0)` gives you the additional information that Alice learned about the contract in commit #0.

Everything following `with` shows the create arguments.

11.3.6 Exercises

To get a better understanding of script, try the following exercises:

1. Write a template for a second type of token.
2. Write a script with two parties and two types of tokens, creating one token of each type for each party and archiving one token for each party, leaving one token of each type in the final ledger view.
3. In [Archive Contracts](#) you tested that Bob cannot archive Alice's token. Can you guess why the submit fails? How can you find out why the submit fails?

Hint: Remember that in [Test for Failure](#) we saw a proper error message for a failing submit.

11.3.7 Next Up

In [Data Types](#) you will learn about Daml's type system, and how you can think of templates as tables and contracts as database rows.

11.4 Data Types

In [Basic Contracts](#), you learnt about contract templates, which specify the types of contracts that can be created on the ledger, and what data those contracts hold in their arguments.

In [Test Templates Using Daml Script](#), you learnt about the script view in Daml Studio, which displays the current ledger state. It shows one table per template, with one row per contract of that type and one column per field in the arguments.

This actually provides a useful way of thinking about templates: like tables in databases. Templates specify a data schema for the ledger:

each template corresponds to a table

each field in the `with` block of a template corresponds to a column in that table

each contract of that type corresponds to a table row

In this section, you'll learn how to create rich data schemas for your ledger. Specifically you'll learn about:

Daml's built-in and native data types

Record types

Hint: Remember that you can load all the code for this section into a folder called `intro3` by running `daml new intro3 --template daml-intro-3`

You have already encountered a few native Daml types: `Party` in [Basic Contracts](#), and `Text` and `ContractId` in [Test Templates Using Daml Script](#). Here are those native types and more:

The below script instantiates each one of these types, manipulates it where appropriate, and tests the result:

(continues on next page)

(continued from previous page)

```
assert (addDays my_date 1 == date 2020 Jan 02)
assert (addRelTime my_time my_rel_time == time (addDays my_date 1) 00 00 00)
```

Despite its simplicity, there are quite a few things to note in this script:

The `import` statements at the top import two packages from the Daml Standard Library, which contain all the date and time related functions we use here as well as the functions used in Daml Scripts. More on packages, imports and the standard library later.

Most of the variables are declared inside a `let` block.

That's because the `script do` block expects script actions like `submit` or `allocateParty`. An integer like `123` is not an action, it's a pure expression, something we can evaluate without any ledger. You can think of the `let` as turning variable declaration into an action.

Most variables do not have annotations to say what type they are.

That's because Daml is very good at *inferring* types. The compiler knows that `123` is an `Int`, so if you declare `my_int = 123`, it can infer that `my_int` is also an `Int`. This means you don't have to write the type annotation `my_int : Int = 123`.

However, if the type is ambiguous so that the compiler can't infer it, you do have to add a type annotation. This is the case for `0.001` which could be any `Numeric n`. Here we specify `0.001 : Decimal` which is a synonym for `Numeric 10`. You can always choose to add type annotations to aid readability.

The `assert` function is an action that takes a boolean value and succeeds with `True` and fails with `False`.

Try putting `assert False` somewhere in a script and see what happens to the script result.

With templates and these native types, it's already possible to write a schema akin to a table in a relational database. Below, `Token` is extended into a simple `CashBalance`, administered by a party in the role of an accountant:

```
template CashBalance
  with
    accountant : Party
    currency : Text
    amount : Decimal
    owner : Party
    account_number : Text
    bank : Party
    bank_address : Text
    bank_telephone : Text
  where
    signatory accountant

cash_balance_test = script do
  accountant <- allocateParty "Bob"
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bank of Bob"

  submit accountant do
    createCmd CashBalance with
      accountant
      currency = "USD"
      amount = 100.0
      owner = alice
      account_number = "ABC123"
      bank = bob
```

(continues on next page)

(continued from previous page)

```
bank_address = "High Street"
bank_telephone = "012 3456 789"
```

11.4.2 Assemble Types

There's quite a lot of information on the `CashBalance` above and it would be nice to be able to give that data more structure. Fortunately, Daml's type system has a number of ways to assemble these native types into much more expressive structures.

11.4.2.1 Tuples

A common task is to group values in a generic way. Take, for example, a key-value pair with a `Text` key and an `Int` value. In Daml, you could use a two-tuple of type `(Text, Int)` to do so. If you wanted to express a coordinate in three dimensions, you could group three `Decimal` values using a three-tuple `(Decimal, Decimal, Decimal)`:

```
import DA.Tuple
import Daml.Script

tuple_test = script do
  let
    my_key_value = ("Key", 1)
    my_coordinate = (1.0 : Decimal, 2.0 : Decimal, 3.0 : Decimal)

    assert (fst my_key_value == "Key")
    assert (snd my_key_value == 1)
    assert (my_key_value._1 == "Key")
    assert (my_key_value._2 == 1)

    assert (my_coordinate == (fst3 my_coordinate, snd3 my_coordinate, thd3 my_
    ↪coordinate))
    assert (my_coordinate == (my_coordinate._1, my_coordinate._2, my_coordinate._3))
```

You can access the data in the tuples using:

functions `fst`, `snd`, `fst3`, `snd3`, `thd3`
 a dot-syntax with field names `_1`, `_2`, `_3`, etc.

Daml supports tuples with up to 20 elements, but accessor functions like `fst` are only included for 2- and 3-tuples.

11.4.2.2 Lists

Lists in Daml take a single type parameter defining the type of thing in the list. So you can have a list of integers `[Int]` or a list of strings `[Text]`, but not a list mixing integers and strings.

That's because Daml is statically and strongly typed. When you get an element out of a list, the compiler needs to know what type that element has.

The below script instantiates a few lists of integers and demonstrates the most important list functions.

```

import DA.List
import Daml.Script

list_test = script do
  let
    empty : [Int] = []
    one = [1]
    two = [2]
    many = [3, 4, 5]

    -- `head` gets the first element of a list
    assert (head one == 1)
    assert (head many == 3)

    -- `tail` gets the remainder after head
    assert (tail one == empty)
    assert (tail many == [4, 5])

    -- `++` concatenates lists
    assert (one ++ two ++ many == [1, 2, 3, 4, 5])
    assert (empty ++ many ++ empty == many)

    -- `::` adds an element to the beginning of a list.
    assert (1 :: 2 :: 3 :: 4 :: 5 :: empty == 1 :: 2 :: many)

```

Note the type annotation on `empty : [Int] = []`. It's necessary because `[]` is ambiguous. It could be a list of integers or of strings, but the compiler needs to know which it is.

11.4.2.3 Records

You can think of records as named tuples with named fields. Declare them using the `data` keyword: `data T = C with`, where `T` is the type name and `C` is the data constructor. In practice, it's a good idea to always use the same name for type and data constructor:

```

data MyRecord = MyRecord with
  my_txt : Text
  my_int : Int
  my_dec : Decimal
  my_list : [Text]

-- Fields of same type can be declared in one line
data Coordinate = Coordinate with
  x, y, z : Decimal

-- Custom data types can also have variables
data KeyValue k v = KeyValue with
  my_key : k
  my_val : v

data Nested = Nested with
  my_coord : Coordinate
  my_record : MyRecord
  my_kv : KeyValue Text Int

record_test = script do

```

(continues on next page)

(continued from previous page)

```

let
  my_record = MyRecord with
    my_txt = "Text"
    my_int = 2
    my_dec = 2.5
    my_list = ["One", "Two", "Three"]

  my_coord = Coordinate with
    x = 1.0
    y = 2.0
    z = 3.0

  -- `my_text_int` has type `KeyValue Text Int`
  my_text_int = KeyValue with
    my_key = "Key"
    my_val = 1

  -- `my_int_decimal` has type `KeyValue Int Decimal`
  my_int_decimal = KeyValue with
    my_key = 2
    my_val = 2.0 : Decimal

  -- If variables are in scope that match field names, we can pick them up
  -- implicitly, writing just `my_coord` instead of `my_coord = my_coord`.
  my_nested = Nested with
    my_coord
    my_record
    my_kv = my_text_int

  -- Fields can be accessed with dot syntax
  assert (my_coord.x == 1.0)
  assert (my_text_int.my_key == "Key")
  assert (my_nested.my_record.my_dec == 2.5)

```

You'll notice that the syntax to declare records is very similar to the syntax used to declare templates. That's no accident because a template is really just a special record. When you write `template Token with`, one of the things that happens in the background is that this becomes a `data Token = Token with`.

In the `assert` statements above, we always compared values of in-built types. If you wrote `assert (my_record == my_record)` in the script, you may be surprised to get an error message `No instance for (Eq MyRecord) arising from a use of '=='`. Equality in Daml is always value equality and we haven't written a function to check value equality for `MyRecord` values. But don't worry, you don't have to implement this rather obvious function yourself. The compiler is smart enough to do it for you, if you use deriving `(Eq)`:

```

data EqRecord = EqRecord with
  my_txt : Text
  my_int : Int
  my_dec : Decimal
  my_list : [Text]
  deriving (Eq)

data MyContainer a = MyContainer with
  contents : a

```

(continues on next page)

(continued from previous page)

```

    deriving (Eq)

eq_test = script do
  let
    eq_record = EqRecord with
      my_txt = "Text"
      my_int = 2
      my_dec = 2.5
      my_list = ["One", "Two", "Three"]

    my_container = MyContainer with
      contents = eq_record
    other_container = MyContainer with
      contents = eq_record

  assert(my_container.contents == eq_record)
  assert(my_container == other_container)

```

`Eq` is what is called a *typeclass*. You can think of a typeclass as being like an interface in other languages: it is the mechanism by which you can define a set of functions (for example, `==` and `/=` in the case of `Eq`) to work on multiple types, with a specific implementation for each type they can apply to.

There are some other typeclasses that the compiler can derive automatically. Most prominently, `Show` to get access to the function `show` (equivalent to `toString` in many languages) and `Ord`, which gives access to comparison operators `<`, `>`, `<=`, `>=`.

It's a good idea to always derive `Eq` and `Show` using `deriving (Eq, Show)`. The record types created using `template T` with `do` this automatically, and the native types have appropriate typeclass instances. Eg `Int` derives `Eq`, `Show` and `Ord`, and `ContractId` derives `Eq` and `Show`.

Records can give the data on `CashBalance` a bit more structure:

```

data Bank = Bank with
  party : Party
  address : Text
  telephone : Text
  deriving (Eq, Show)

data Account = Account with
  owner : Party
  number : Text
  bank : Bank
  deriving (Eq, Show)

data Cash = Cash with
  currency : Text
  amount : Decimal
  deriving (Eq, Show)

template CashBalance
  with
    accountant : Party
    cash : Cash
    account : Account
  where

```

(continues on next page)

(continued from previous page)

```

signatory accountant

cash_balance_test = script do
  accountant <- allocateParty "Bob"
  owner <- allocateParty "Alice"
  bank_party <- allocateParty "Bank"
  let
    bank = Bank with
      party = bank_party
      address = "High Street"
      telephone = "012 3456 789"
    account = Account with
      owner
      bank
      number = "ABC123"
    cash = Cash with
      currency = "USD"
      amount = 100.0

  submit accountant do
    createCmd CashBalance with
      accountant
      cash
      account
  pure ()

```

If you look at the resulting script view, you'll see that this still gives rise to one table. The records are expanded out into columns using dot notation.

11.4.2.4 Variants and Pattern Matching

Suppose now that you also wanted to keep track of cash in hand. Cash in hand doesn't have a bank, but you can't just leave `bank` empty. Daml doesn't have an equivalent to `null`. Variants can express that cash can either be in hand or at a bank:

```

data Bank = Bank with
  party : Party
  address : Text
  telephone : Text
  deriving (Eq, Show)

data Account = Account with
  number : Text
  bank : Bank
  deriving (Eq, Show)

data Cash = Cash with
  currency : Text
  amount : Decimal
  deriving (Eq, Show)

data Location
  = InHand
  | InAccount Account

```

(continues on next page)

(continued from previous page)

```

    deriving (Eq, Show)

template CashBalance
  with
    accountant : Party
    owner      : Party
    cash       : Cash
    location   : Location
  where
    signatory accountant

cash_balance_test = do
  accountant <- allocateParty "Bob"
  owner      <- allocateParty "Alice"
  bank_party <- allocateParty "Bank"
  let
    bank = Bank with
      party = bank_party
      address = "High Street"
      telephone = "012 3456 789"
    account = Account with
      bank
      number = "ABC123"
    cash = Cash with
      currency = "USD"
      amount = 100.0

  submit accountant do
    createCmd CashBalance with
      accountant
      owner
      cash
      location = InHand

  submit accountant do
    createCmd CashBalance with
      accountant
      owner
      cash
      location = InAccount account

```

The way to read the declaration of `Location` is *A Location either has value `InHand` OR has a value `InAccount` a where a is of type `Account`*. This is quite an explicit way to say that there may or may not be an `Account` associated with a `CashBalance` and gives both cases suggestive names.

Another option is to use the built-in `Optional` type. The `None` value of type `Optional a` is the closest Daml has to a null value:

```

data Optional a
  = None
  | Some a
  deriving (Eq, Show)

```

Variant types where none of the data constructors take a parameter are called enums:

```
data DayOfWeek
= Monday
| Tuesday
| Wednesday
| Thursday
| Friday
| Saturday
| Sunday
deriving (Eq, Show)
```

To access the data in variants, you need to distinguish the different possible cases. For example, you can no longer access the account number of a `Location` directly, because if it is `InHand`, there may be no account number.

To do this, you can use *pattern matching* and either throw errors or return compatible types for all cases:

```
{-
-- Commented out as `Either` is defined in the standard library.
data Either a b
  = Left a
  | Right b
-}

variant_access_test = script do
  let
    l : Either Int Text = Left 1
    r : Either Int Text = Right "r"

    -- If we know that `l` is a `Left`, we can error on the `Right` case.
    l_value = case l of
      Left i -> i
      Right i -> error "Expecting Left"
    -- Comment out at your own peril
    {-
    r_value = case r of
      Left i -> i
      Right i -> error "Expecting Left"
    -}

    -- If we are unsure, we can return an `Optional` in both cases
    ol_value = case l of
      Left i -> Some i
      Right i -> None
    or_value = case r of
      Left i -> Some i
      Right i -> None

    -- If we don't care about values or even constructors, we can use wildcards
    l_value2 = case l of
      Left i -> i
      Right _ -> error "Expecting Left"
    l_value3 = case l of
      Left i -> i
      _ -> error "Expecting Left"
```

(continues on next page)

(continued from previous page)

```

day = Sunday
weekend = case day of
  Saturday -> True
  Sunday   -> True
  _        -> False

assert (l_value == 1)
assert (l_value2 == 1)
assert (l_value3 == 1)
assert (ol_value == Some 1)
assert (or_value == None)
assert weekend

```

11.4.3 Manipulate Data

You've got all the ingredients to build rich types expressing the data you want to be able to write to the ledger, and you have seen how to create new values and read fields from values. But how do you manipulate values once created?

All data in Daml is immutable, meaning once a value is created, it will never change. Rather than changing values, you create new values based on old ones with some changes applied:

```

manipulation_demo = script do
  let
    eq_record = EqRecord with
      my_txt = "Text"
      my_int = 2
      my_dec = 2.5
      my_list = ["One", "Two", "Three"]

    -- A verbose way to change `eq_record`
    changed_record = EqRecord with
      my_txt = eq_record.my_txt
      my_int = 3
      my_dec = eq_record.my_dec
      my_list = eq_record.my_list

    -- A better way
    better_changed_record = eq_record with
      my_int = 3

    record_with_changed_list = eq_record with
      my_list = "Zero" :: eq_record.my_list

  assert (eq_record.my_int == 2)
  assert (changed_record == better_changed_record)

  -- The list on `eq_record` can't be changed.
  assert (eq_record.my_list == ["One", "Two", "Three"])
  -- The list on `record_with_changed_list` is a new one.
  assert (record_with_changed_list.my_list == ["Zero", "One", "Two", "Three"])

```

`changed_record` and `better_changed_record` are each a copy of `eq_record` with the field `my_int` changed. `better_changed_record` shows the recommended way to change fields on a

record. The syntax is almost the same as for a new record, but the record name is replaced with the old value: `eq_record` with instead of `EqRecord` with. The `with` block no longer needs to give values to all fields of `EqRecord`. Any missing fields are taken from `eq_record`.

Throughout the script, `eq_record` never changes. The expression `"Zero" :: eq_record.my_list` doesn't change the list in-place, but creates a new list, which is `eq_record.my_list` with an extra element in the beginning.

11.4.4 Contract Keys

Daml's type system lets you store richly structured data on Daml templates, but just like most database schemas have more than one table, Daml contract models often have multiple templates that reference each other. For example, you may not want to store your bank and account information on each individual cash balance contract, but instead store those on separate contracts.

You have already met the type `ContractId a`, which references a contract of type `a`. The below shows a contract model where `Account` is split out into a separate template and referenced by `ContractId`, but it also highlights a big problem with that kind of reference: just like data, contracts are immutable. They can only be created and archived, so if you want to change the data on a contract, you end up archiving the original contract and creating a new one with the changed data. That makes contract IDs very unstable, and can cause stale references.

```
data Bank = Bank with
  party : Party
  address: Text
  telephone : Text
  deriving (Eq, Show)

template Account
  with
    accountant : Party
    owner : Party
    number : Text
    bank : Bank
  where
    signatory accountant

data Cash = Cash with
  currency : Text
  amount : Decimal
  deriving (Eq, Show)

template CashBalance
  with
    accountant : Party
    cash : Cash
    account : ContractId Account
  where
    signatory accountant

id_ref_test = do
  accountant <- allocateParty "Bob"
  owner <- allocateParty "Alice"
  bank_party <- allocateParty "Bank"
  let
```

(continues on next page)

(continued from previous page)

```

bank = Bank with
  party = bank_party
  address = "High Street"
  telephone = "012 3456 789"
cash = Cash with
  currency = "USD"
  amount = 100.0

accountCid <- submit accountant do
  createCmd Account with
    accountant
    owner
    bank
    number = "ABC123"

balanceCid <- submit accountant do
  createCmd CashBalance with
    accountant
    cash
    account = accountCid

-- Now the accountant updates the telephone number for the bank on the account
Some account <- queryContractId accountant accountCid
new_accountCid <- submit accountant do
  archiveCmd accountCid
  cid <- createCmd account with
    bank = account.bank with
      telephone = "098 7654 321"
  pure cid

-- The `account` field on the balance now refers to the archived
-- contract, so this will fail.
Some balance <- queryContractId accountant balanceCid
optAccount <- queryContractId accountant balance.account
optAccount === None

```

The script above uses the `queryContractId` function, which retrieves the arguments of an active contract using its contract ID. If there is no active contract with the given identifier visible to the given party, `queryContractId` returns `None`. Here, we use a pattern match on `Some` which will abort the script if `queryContractId` returns `None`.

Note that, for the first time, the party submitting a transaction is doing more than one thing as part of that transaction. To create `new_account`, the accountant archives the old account and creates a new account, all in one transaction. More on building transactions in [Composing Choices](#).

You can define *stable* keys for contracts using the `key` and `maintainer` keywords. `key` defines the primary key of a template, with the ability to look up contracts by key, and a uniqueness constraint in the sense that only one contract of a given template and with a given key value can be active at a time:

```

data Bank = Bank with
  party : Party
  address: Text
  telephone : Text
  deriving (Eq, Show)

```

(continues on next page)

(continued from previous page)

```

data AccountKey = AccountKey with
  accountant : Party
  number : Text
  bank_party : Party
  deriving (Eq, Show)

template Account
  with
    accountant : Party
    owner : Party
    number : Text
    bank : Bank
  where
    signatory accountant

    key AccountKey with
      accountant
      number
      bank_party = bank.party
    : AccountKey
    maintainer key.accountant

data Cash = Cash with
  currency : Text
  amount : Decimal
  deriving (Eq, Show)

template CashBalance
  with
    accountant : Party
    cash : Cash
    account : AccountKey
  where
    signatory accountant

id_ref_test = do
  accountant <- allocateParty "Bob"
  owner <- allocateParty "Alice"
  bank_party <- allocateParty "Bank"
  let
    bank = Bank with
      party = bank_party
      address = "High Street"
      telephone = "012 3456 789"
    cash = Cash with
      currency = "USD"
      amount = 100.0

  accountCid <- submit accountant do
    createCmd Account with
      accountant
      owner
      bank
      number = "ABC123"

```

(continues on next page)

(continued from previous page)

```

Some account <- queryContractId accountant accountCid
balanceCid <- submit accountant do
  createCmd CashBalance with
    accountant
    cash
    account = key account

-- Now the accountant updates the telephone number for the bank on the account
Some account <- queryContractId accountant accountCid
new_accountCid <- submit accountant do
  archiveCmd accountCid
  cid <- createCmd account with
    bank = account.bank with
      telephone = "098 7654 321"
  pure cid

-- Thanks to contract keys, the current account contract is fetched
Some balance <- queryContractId accountant balanceCid
Some (new_cid, new_account : Account) <- queryContractKey accountant balance.
↪ account
new_cid === new_accountCid
new_account /= account

```

Since Daml is designed to run on distributed systems, you have to assume that there is no global entity that can guarantee uniqueness, which is why each `key` expression must come with a `maintainer` expression. `maintainer` takes one or several parties, all of which have to be signatories of the contract and be part of the key. That way the index can be partitioned amongst sets of maintainers, and each set of maintainers can independently ensure the uniqueness constraint on their piece of the index. The constraint that maintainers are part of the key is ensured by only having the variable `key` in each `maintainer` expression.

Instead of calling `queryContractId` to get the contract arguments associated with a given contract identifier, use `queryContractKey`. `queryContractKey` takes a value of type `AccountKey` and returns an optional tuple. In this case, that optional tuple is of type `Optional (ContractId Account, Account)`. After archiving the old account (to change the phone number), you can still fetch the account using the existing, unmodified `balance`. Where the `ContractId Account` is different for the new account, the `AccountKey` is the same.

When calling `queryContractKey` a single key type could be used as the key for multiple templates. Consequently, you need to tell the compiler what type of contract the key is referencing. You can do that with a type annotation on the returned value.

11.4.5 Next Up

You can now define data schemas for the ledger, read, write and delete data from the ledger, and use keys to reference and look up data in a stable fashion.

In [Transform Data Using Choices](#) you'll learn how to define data transformations and give other parties the right to manipulate data in restricted ways.

11.5 Transform Data Using Choices

In the example in [Contract Keys](#) the accountant party wanted to change some data on a contract. They did so by archiving the contract and re-creating it with the updated data. That works because the accountant is the sole signatory on the `Account` contract defined there.

But what if the accountant wanted to allow the bank to change their own telephone number? Or what if the owner of a `CashBalance` should be able to transfer ownership to someone else?

In this section you will learn about how to define simple data transformations using *choices* and how to delegate the right to exercise these choices to other parties.

Hint: Remember that you can load all the code for this section into a folder called `intro4` by running `daml new intro4 --template daml-intro-4`

11.5.1 Choices as Methods

If you think of templates as classes and contracts as objects, where are the methods?

Take as an example a `Contact` contract on which the contact owner wants to be able to change the telephone number, just like on the `Account` in [Contract Keys](#). Rather than requiring them to manually look up the contract, archive the old one and create a new one, you can provide them a convenience method on `Contact`:

```
template Contact
  with
    owner : Party
    party : Party
    address : Text
    telephone : Text
  where
    signatory owner
    observer party

    choice UpdateTelephone
      : ContractId Contact
      with
        newTelephone : Text
      controller owner
      do
        create this with
          telephone = newTelephone
```

The above defines a choice called `UpdateTelephone`. Choices are part of a contract template. They're permissioned functions that result in an `Update`. Using choices, authority can be passed around, allowing the construction of complex transactions.

Let's unpack the code snippet above:

The first line, `choice UpdateTelephone` indicates a choice definition, `UpdateTelephone` is the name of the choice. It starts a new block in which that choice is defined.
`: ContractId Contact` is the return type of the choice.

This particular choice archives the current `Contact`, and creates a new one. What it returns is a reference to the new contract, in the form of a `ContractId Contact`

The following `with` block is that of a record. Just like with templates, in the background, a new record type is declared: `data UpdateTelephone = UpdateTelephone with`

The line `controller owner` says that this choice is *controlled by* `owner`, meaning `owner` is the only party that is allowed to exercise them.

The `do` starts a block defining the action the choice should perform when exercised. In this case a new `Contact` is created.

The new `Contact` is created using `this with`. `this` is a special value available within the `where` block of templates and takes the value of the current contract's arguments.

There is nothing here explicitly saying that the current `Contact` should be archived. That's because choices are *consuming* by default. That means when the above choice is exercised on a contract, that contract is archived.

As mentioned in [Data Types](#), within a choice we use `create` instead of `createCmd`. Whereas `createCmd` builds up a list of commands to be sent to the ledger, `create` builds up a more flexible `Update` that is executed directly by the ledger. You might have noticed that `create` returns an `Update (ContractId Contact)`, not a `ContractId Contact`. As a `do` block always returns the value of the last statement within it, the whole `do` block returns an `Update`, but the return type on the choice is just a `ContractId Contact`. This is a convenience. Choices *always* return an `Update` so for readability it's omitted on the type declaration of a choice.

Now to exercise the new choice in a script:

```
choice_test = do
  owner <- allocateParty "Alice"
  party <- allocateParty "Bob"

  contactCid <- submit owner do
    createCmd Contact with
      owner
      party
      address = "1 Bobstreet"
      telephone = "012 345 6789"

  -- Bob can't change his own telephone number as Alice controls
  -- that choice.
  submitMustFail party do
    exerciseCmd contactCid UpdateTelephone with
      newTelephone = "098 7654 321"

  newContactCid <- submit owner do
    exerciseCmd contactCid UpdateTelephone with
      newTelephone = "098 7654 321"

  Some newContact <- queryContractId owner newContactCid

  assert (newContact.telephone == "098 7654 321")
```

You exercise choices using the `exercise` function, which takes a `ContractId a`, and a value of type `c`, where `c` is a choice on template `a`. Since `c` is just a record, you can also just fill in the choice parameters using the `with` syntax you are already familiar with.

`exerciseCmd` returns a `Commands r` where `r` is the return type specified on the choice, allowing the new `ContractId Contact` to be stored in the variable `newContactCid`. Just like for `createCmd`

and `create`, there is also `exerciseCmd` and `exercise`. The versions with the `cmd` suffix is always used on the client side to build up the list of commands on the ledger. The versions without the suffix are used within choices and are executed directly on the server.

There is also `createAndExerciseCmd` and `createAndExercise` which we have seen in the previous section. This allows you to create a new contract with the given arguments and immediately exercise a choice on it. For a consuming choice, this archives the contract so the contract is created and archived within the same transaction.

11.5.2 Choices as Delegation

Up to this point all the contracts only involved one party. `party` may have been stored as `Party` field in the above, which suggests they are actors on the ledger, but they couldn't see the contracts, nor change them in any way. It would be reasonable for the party for which a `Contact` is stored to be able to update their own address and telephone number. In other words, the owner of a `Contact` should be able to *delegate* the right to perform a certain kind of data transformation to `party`.

The below demonstrates this using an `UpdateAddress` choice and corresponding extension of the script:

```
choice UpdateAddress
  : ContractId Contact
  with
    newAddress : Text
  controller party
  do
    create this with
      address = newAddress
```

```
newContactCid <- submit party do
  exerciseCmd newContactCid UpdateAddress with
    newAddress = "1-10 Bobstreet"

Some newContact <- queryContractId owner newContactCid

assert (newContact.address == "1-10 Bobstreet")
```

If you open the script view in the IDE, you will notice that Bob sees the `Contact`. This is because `party` is specified as an observer in the template, and in this case Bob is the `party`. More on observers later, but in short, they get to see any changes to the contract.

11.5.3 Choices In the Ledger Model

In [Basic Contracts](#) you learned about the high-level structure of a Daml ledger. With choices and the `exercise` function, you have the next important ingredient to understand the structure of the ledger and transactions.

A *transaction* is a list of *actions*, and there are just four kinds of action: `create`, `exercise`, `fetch` and `key assertion`.

- A `create` action creates a new contract with the given arguments and sets its status to `active`.
- A `fetch` action checks the existence and activeness of a contract.

An `exercise` action exercises a choice on a contract resulting in a transaction (list of sub-actions) called the `consequences`. Exercises come in two kinds called `consuming` and `non-consuming`. `consuming` is the default kind and changes the contract's status from `active` to `archived`.

A `key assertion` records the assertion that the given contract key (see [Contract Keys](#)) is not assigned to any active contract on the ledger.

Each action can be visualized as a tree, where the action is the root node, and its children are its consequences. Every consequence may have further consequences. As `fetch`, `create` and `key assertion` actions have no consequences, they are always leaf nodes. You can see the actions and their consequences in the transaction view of the above script:

```
Transactions:

            owner = 'Alice'; party = 'Bob'; address = "1 Bobstreet";
    ↪telephone = "098 7654 321"

TX 3 1970-01-01T00:00:00Z (Contact:69:20)
#3:0
├── disclosed to (since): 'Alice' (3), 'Bob' (3)
└─> 'Bob' exercises UpdateAddress on #2:1 (Contact:Contact)
    with
        newAddress = "1-10 Bobstreet"
    children:
    #3:1
    ├── disclosed to (since): 'Alice' (3), 'Bob' (3)
    └─> 'Alice' creates Contact:Contact
        with
            owner = 'Alice';
            party = 'Bob';
            address = "1-10 Bobstreet";
```

(continues on next page)

(continued from previous page)

```

        telephone = "098 7654 321"

Active contracts:  #3:1

Return value: {}

```

There are four commits corresponding to the four `submit` statements in the script. Within each commit, we see that it's actually actions that have IDs of the form `#commit_number:action_number`. Contract IDs are just the ID of their `create` action.

So commits #2 and #3 contain `exercise` actions with IDs #2:0 and #3:0. The `create` actions of the updated `Contact` contracts, #2:1 and #3:1, are indented and found below a line reading `children:`, making the tree structure apparent.

11.5.3.1 The Archive Choice

You may have noticed that there is no archive action. That's because `archive cid` is just shorthand for `exercise cid Archive`, where `Archive` is a choice implicitly added to every template, with the signatories as controllers.

11.5.4 A Simple Cash Model

With the power of choices, you can build your first interesting model: issuance of cash IOUs (I owe you). The model presented here is simpler than the one in [Data Types](#) as it's not concerned with the location of the physical cash, but merely with liabilities:

```

-- Copyright (c) 2024 Digital Asset (Switzerland) GmbH and/or its affiliates. All
-- rights reserved.
-- SPDX-License-Identifier: Apache-2.0

module SimpleIou where

import Daml.Script

data Cash = Cash with
  currency : Text
  amount   : Decimal
  deriving (Eq, Show)

template SimpleIou
  with
    issuer : Party
    owner  : Party
    cash   : Cash
  where
    signatory issuer
    observer  owner

    choice Transfer
      : ContractId SimpleIou
      with

```

(continues on next page)

(continued from previous page)

```

    newOwner : Party
    controller owner
  do
    create this with owner = newOwner

test_iou = script do
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"
  charlie <- allocateParty "Charlie"
  dora <- allocateParty "Dora"

  -- Dora issues an Iou for $100 to Alice.
  iou <- submit dora do
    createCmd SimpleIou with
      issuer = dora
      owner = alice
      cash = Cash with
        amount = 100.0
        currency = "USD"

  -- Alice transfers it to Bob.
  iou2 <- submit alice do
    exerciseCmd iou Transfer with
      newOwner = bob

  -- Bob transfers it to Charlie.
  submit bob do
    exerciseCmd iou2 Transfer with
      newOwner = charlie

```

The above model is fine as long as everyone trusts Dora. Dora could revoke the *SimpleIou* at any point by archiving it. However, the provenance of all transactions would be on the ledger so the owner could prove that Dora was dishonest and cancelled her debt.

11.5.5 Next Up

You can now store and transform data on the ledger, even giving other parties specific write access through choices.

In [Add Constraints to a Contract](#), you will learn how to restrict data and transformations further. In that context, you will also learn about time on Daml ledgers, `do` blocks and `<-` notation within those.

11.6 Add Constraints to a Contract

You will often want to constrain the data stored or the allowed data transformations in your contract models. In this section, you will learn about the two main mechanisms provided in Daml:

- The `ensure` keyword.

- The `assert`, `abort` and `error` keywords.

To make sense of the latter, you'll also learn more about the `Update` and `Script` types and `do` blocks, which will be good preparation for [Composing Choices](#), where you will use `do` blocks to compose choices into complex transactions.

Lastly, you will learn about time on the ledger and in Daml Script.

Hint: Remember that you can load all the code for this section into a folder called `intro5` by running `daml new intro5 --template daml-intro-5`

11.6.1 Template Preconditions

The first kind of restriction you may want to put on the contract model are called *template pre-conditions*. These are simply restrictions on the data that can be stored on a contract from that template.

Suppose, for example, that the `SimpleIou` contract from [A Simple Cash Model](#) should only be able to store positive amounts. You can enforce this using the `ensure` keyword:

```
template SimpleIou
  with
    issuer : Party
    owner  : Party
    cash   : Cash
  where
    signatory issuer
    observer  owner

    ensure cash.amount > 0.0
```

The `ensure` keyword takes a single expression of type `Bool`. If you want to add more restrictions, use logical operators `&&`, `||` and `not` to build up expressions. The below shows the additional restriction that currencies are three capital letters:

```
&& T.length cash.currency == 3
&& T.isUpper cash.currency
```

Hint: The `T` here stands for the `DA.Text` standard library which has been imported using `import DA.Text as T`:

```
test_restrictions = do
  alice <- allocateParty "Alice"
  bob   <- allocateParty "Bob"
  dora  <- allocateParty "Dora"

  -- Dora can't issue negative Ious.
  submitMustFail dora do
    createCmd SimpleIou with
      issuer = dora
      owner  = alice
      cash = Cash with
        amount = -100.0
        currency = "USD"

  -- Or even zero Ious.
  submitMustFail dora do
```

(continues on next page)

(continued from previous page)

```

createCmd SimpleIou with
  issuer = dora
  owner = alice
  cash = Cash with
    amount = 0.0
    currency = "USD"

-- Nor positive Ious with invalid currencies.
submitMustFail dora do
  createCmd SimpleIou with
    issuer = dora
    owner = alice
    cash = Cash with
      amount = 100.0
      currency = "Swiss Francs"

-- But positive Ious still work, of course.
iou <- submit dora do
  createCmd SimpleIou with
    issuer = dora
    owner = alice
    cash = Cash with
      amount = 100.0
      currency = "USD"

```

11.6.2 Assertions

A second common kind of restriction is one on data transformations.

For example, the simple iou in [A Simple Cash Model](#) allowed the no-op where the owner transfers to themselves. You can prevent that using an `assert` statement, which you have already encountered in the context of scripts.

`assert` does not return an informative error so often it's better to use the function `assertMsg`, which takes a custom error message:

```

choice Transfer
  : ContractId SimpleIou
  with
    newOwner : Party
  controller owner
  do
    assertMsg "newOwner cannot be equal to owner." (owner /= newOwner)
    create this with owner = newOwner

```

```

-- Alice can't transfer to herself...
submitMustFail alice do
  exerciseCmd iou Transfer with
    newOwner = alice

-- ... but can transfer to Bob.
iou2 <- submit alice do
  exerciseCmd iou Transfer with
    newOwner = bob

```

Similarly, you can write a `Redeem` choice, which allows the `owner` to redeem an `Iou` during business hours on weekdays. The `Redeem` choice implementation below confirms that `getTime` returns a value that is during business hours on weekdays. If all those checks pass, the choice does not do anything other than archive the `SimpleIou`. (This assumes that actual cash changes hands off-ledger:)

```
choice Redeem
: ()
controller owner
do
  now <- getTime
  let
    today = toDateUTC now
    dow = dayOfWeek today
    timeofday = now `subTime` time today 0 0 0
    hrs = convertRelTimeToMicroseconds timeofday / 3600000000
  if (hrs < 8 || hrs > 18) then
    abort $ "Cannot redeem outside business hours. Current time: " <> show
    ↪timeofday
  else case dow of
    Saturday -> abort "Cannot redeem on a Saturday."
    Sunday -> abort "Cannot redeem on a Sunday."
    _ -> return ()
```

In the above example, the time is taken apart into day of week and hour of day using standard library functions from `DA.Date` and `DA.Time`. The hour of the day is checked to be in the range from 8 to 18. The day of week is checked to not be Saturday or Sunday.

The following example shows how the `Redeem` choice is exercised in a script:

```
-- June 1st 2019 is a Saturday.
setTime (time (date 2019 Jun 1) 0 0 0)
-- Bob cannot redeem on a Saturday.
submitMustFail bob do
  exerciseCmd iou2 Redeem

-- Not even at mid-day.
passTime (hours 12)
-- Bob cannot redeem on a Saturday.
submitMustFail bob do
  exerciseCmd iou2 Redeem

-- Bob also cannot redeem at 6am on a Monday.
passTime (hours 42)
submitMustFail bob do
  exerciseCmd iou2 Redeem

-- Bob can redeem at 8am on Monday.
passTime (hours 2)
submit bob do
  exerciseCmd iou2 Redeem
```

For the purposes of testing the `Redeem` choice, the above code sets and advances the ledger time with the `setTime` and `passTime` functions respectively. Exercising the choice should fail or should not fail depending on the day of week and the time of day. While that is straightforward, the issue of time on a Daml ledger is worthy of more discussion.

11.6.3 Time on Daml Ledgers

Each transaction on a Daml ledger has two timestamps: the *ledger time* (LT) and the *record time* (RT).

Ledger time (LT) is the time associated with a transaction in the ledger model, as determined by the participant. It is the time of a transaction from a business and application perspective. When you call `getTime`, it is the LT that is returned. The LT is used when reasoning about related transactions and commits. The LT can be compared with other LTs to guarantee model consistency. For example, LTs are used to enforce that no transaction depends on a contract that does not exist. This is the requirement known as *causal monotonicity*.

Record time (RT) is the time assigned by the persistence layer. It represents the time that the transaction is *physically* recorded. For example, The backing database ledger has assigned the timestamp of such-and-such time to this transaction. The only purpose of the RT is to ensure that transactions are being recorded in a timely manner.

Each Daml ledger has a policy on the allowed difference between LT and RT called the *skew*. A consistent zero-skew is not feasible because this is a distributed system. If it is too far off, the transaction will be rejected. This is the requirement known as *bounded skew*. The RT is not relevant beyond this determination of skew.

Returning to the theme of *business hours*, consider the following example: Suppose that the ledger had a skew of 10 seconds. At 17:59:55, just before the end of business hours, Alice submits a transaction to redeem an iou. One second later, the transaction is assigned an LT of 17:59:56. However, there still may be a few seconds before the transaction is persisted to the underlying storage. For example, the transaction might be written in the underlying backing store at 18:00:06, *after business hours*. Because LT is within business hours and $LT - RT \leq 10$ seconds, the transaction will not be rejected.

For details, see [Background concepts - time](#).

11.6.3.1 Time in Test Scripts

For tests, you can set time using the following functions:

`setTime`, which sets the ledger time to the given time.

`passTime`, which takes a `RelTime` (a relative time) and moves the ledger by that much.

On a distributed Daml ledger, there are no guarantees that LT or RT are strictly increasing. The only guarantee is that ledger time is increasing *with causality*. That is, if a transaction TX2 depends on a transaction TX1, then the ledger enforces that the LT of TX2 is greater than or equal to that of TX1.

The following script illustrates that idea by moving the logical time back by three days and then trying to exercise a choice on a contract that *hasn't been created yet*. That fails, as you would hope.

```
iou3 <- submit dora do
  createCmd SimpleIou with
    issuer = dora
    owner = alice
    cash = Cash with
      amount = 100.0
      currency = "USD"

passTime (days (-3))
submitMustFail alice do
  exerciseCmd iou3 Redeem
```

11.6.4 Actions and `do` Blocks

You have come across `do` blocks and `<-` notations in two contexts by now: `Script` and `Update`. Both of these are examples of an `Action`, also called a *Monad* in functional programming. You can construct `Actions` conveniently using `do` notation.

Understanding `Actions` and `do` blocks is therefore crucial to being able to construct correct contract models and test them, so this section will explain them in some detail.

11.6.4.1 Pure Expressions Compared to Actions

Expressions in Daml are pure in the sense that they have no side-effects: they neither read nor modify any external state. If you know the value of all variables in scope and write an expression, you can work out the value of that expression on pen and paper.

However, the expressions you've seen that used the `<-` notation are not like that. For example, take `getTime`, which is an `Action`. Here's the example we used earlier:

```
now <- getTime
```

You cannot work out the value of `now` based on any variable in scope. To put it another way, there is no expression `expr` that you could put on the right hand side of `now = expr`. To get the ledger time, you must be in the context of a submitted transaction, and then look at that context.

Similarly, you've come across `fetch`. If you have `cid : ContractId Account` in scope and you come across the expression `fetch cid`, you can't evaluate that to an `Account` so you can't write `account = fetch cid`. To do so, you'd have to have a ledger you can look that contract ID up on.

11.6.4.2 Actions and Impurity

Actions are a way to handle such `impure` expressions. `Action a` is a type class with a single parameter `a`, and `Update` and `Script` are instances of `Action`. A value of such a type `m a` where `m` is an instance of `Action` can be interpreted as a recipe for an action of type `m`, which, when executed, returns a value `a`.

You can always write a recipe using just pen and paper, but you can't cook it up unless you are in the context of a kitchen with the right ingredients and utensils. When cooking the recipe you have an effect – you change the state of the kitchen – and a return value – the thing you leave the kitchen with.

An `Update a` is a recipe to update a Daml ledger, which, when committed, has the effect of changing the ledger, and returns a value of type `a`. An update to a Daml ledger is a transaction so equivalently, an `Update a` is a recipe to construct a transaction, which, when executed in the context of a ledger, returns a value of type `a`.

A `Script a` is a recipe for a test, which, when performed against a ledger, has the effect of changing the ledger in ways analogous to those available via the API, and returns a value of type `a`.

Expressions like `getTime`, `allocateParty party`, `passTime time`, `submit party` commands, `create contract` and `exercise choice` should make more sense in that light. For example:

`getTime : Update Time` is the recipe for an empty transaction that also happens to return a value of type `Time`.

`passTime (days 10) : Script ()` is a recipe for a transaction that doesn't submit any transactions, but has the side-effect of changing the LT of the test ledger. It returns `()`, also called `Unit` and can be thought of as a zero-tuple.

`create iou : Update (ContractId Iou)`, where `iou : Iou` is a recipe for a transaction consisting of a single `create` action, and returns the contract id of the created contract if successful.

`submit alice (createCmd iou) : Script (ContractId Iou)` is a recipe for a script in which Alice sends the command `createCmd iou` to the ledger which produces a transaction and a return value of type `ContractId Iou` and returns that back to Alice.

`Commands` is a bit more restricted than `Script` and `Update` as it represents a list of independent commands sent to the ledger. You can still use `do` blocks but if you have more than one command in a single `do` block you need to enable the `ApplicativeDo` extension at the beginning of your file. In addition to that, the last statement in such a `do` block must be of the form `return expr` or `pure expr`. `Applicative` is a more restricted version of `Action` that enforces that there are no dependencies between commands. If you do have dependencies between commands, you can always wrap it in a choice in a helper template and call that via `createAndExerciseCmd` just like we did to call `fetchByKey`. Alternatively, if you do not need them to be part of the same transaction, you can make multiple calls to `submit`:

```
{-# LANGUAGE ApplicativeDo #-}
module Restrictions where
```

11.6.4.3 Chain Actions With `do` Blocks

An action followed by another action, possibly depending on the result of the first action, is just another action. Specifically:

A transaction is a list of actions. So a transaction followed by another transaction is again a transaction.

A script is a list of interactions with the ledger (`submit`, `allocateParty`, `passTime`, etc). So a script followed by another script is again a script.

This is where `do` blocks come in. `do` blocks allow you to build complex actions from simple ones, using the results of earlier actions in later ones:

```
sub_script1 (alice, dora) = do
  submit dora do
    createCmd SimpleIou with
      issuer = dora
      owner = alice
      cash = Cash with
        amount = 100.0
        currency = "USD"

sub_script2 = do
  passTime (days 1)
  passTime (days (-1))
  return 42

sub_script3 (bob, dora) = do
  submit dora do
    createCmd SimpleIou with
```

(continues on next page)

(continued from previous page)

```

    issuer = dora
    owner = bob
    cash = Cash with
      amount = 100.0
      currency = "USD"

main_ : Script () = do
  dora <- allocateParty "Dora"
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"

  iou1 <- sub_script1 (alice, dora)
  sub_script2
  iou2 <- sub_script3 (bob, dora)

  submit dora do
    archiveCmd iou1
    archiveCmd iou2
    pure ()

```

Above, we see `do` blocks in action for both `Script` and `Update`.

11.6.4.4 Wrap Values in Actions

You may already have noticed the use of `return` in the `redeem` choice. `return x` is a no-op action which returns value `x` so `return 42 : Update Int`. Since `do` blocks always return the value of their last action, `sub_script2 : Script Int`.

11.6.5 Failing Actions

Not only are `Update` and `Script` examples of `Action`, they are both examples of actions that can fail, e.g. because a transaction is illegal or the party retrieved via `allocateParty` doesn't exist on the ledger.

Each has a special action `abort txt` that represents failure, and that takes on type `Update ()` or `Script ()` depending on context.

Transactions succeed or fail *atomically* as a whole. Scripts on the other hand do not fail atomically: while each `submit` is atomic, if a `submit` succeeded and the script fails later, the effects of that `submit` will still be applied to the ledger.

The last expression in the `do` block of the `Redeem` choice is a pattern matching expression on `dow`. It has type `Update ()` and is either an `abort` or `return` depending on the day of week. So during the week, it's a no-op and on weekends, it's the special failure action. Thanks to the atomicity of transactions, no transaction can ever make use of the `Redeem` choice on weekends, because it fails the entire transaction.

11.6.6 A Sample Action

If the above didn't make complete sense, here's another example to explain what actions are more generally, by creating a new type that is also an action. `CoinGame a` is an `Action a` in which a `Coin` is flipped. The `Coin` is a pseudo-random number generator and each flip has the effect of changing the random number generator's state. Based on the `Heads` and `Tails` results, a return value of type `a` is calculated:

```
data Face = Heads | Tails
  deriving (Eq, Show, Enum)

data CoinGame a = CoinGame with
  play : Coin -> (Coin, a)

flipCoin : CoinGame Face
getCoin  : Script Coin
```

A `CoinGame a` exposes a function `play` which takes a `Coin` and returns a new `Coin` and a result `a`. More on the `->` syntax for functions later.

`Coin` and `play` are deliberately left obscure in the above. All you have is an action `getCoin` to get your hands on a `Coin` in a `Script` context and an action `flipCoin` which represents the simplest possible game: a single coin flip resulting in a `Face`.

You can't play any `CoinGame` game on pen and paper as you don't have a coin, but you can write down a script or recipe for a game:

```
coin_test = do
  -- The coin is pseudo-random on LT so change the parameter to change the game.
  setTime (time (date 2019 Jun 1) 0 0 0)
  passTime (seconds 2)
  coin <- getCoin
  let
    game = do
      f1r <- flipCoin
      f2r <- flipCoin
      f3r <- flipCoin

      if all (== Heads) [f1r, f2r, f3r]
      then return "Win"
      else return "Loss"
    (newCoin, result) = game.play coin

  assert (result == "Win")
```

The game expression is a `CoinGame` in which a coin is flipped three times. If all three tosses return `Heads`, the result is `"Win"`, or else `"Loss"`.

In a `Script` context you can get a `Coin` using the `getCoin` action, which uses the LT to calculate a seed, and play the game.

Somehow the `Coin` is threaded through the various actions. If you want to look through the looking glass and understand in-depth what's going on, you can look at the source file to see how the `CoinGame` action is implemented, though be warned that the implementation uses a lot of Daml features we haven't introduced yet in this introduction.

More generally, if you want to learn more about Actions (aka Monads), we recommend a general

course on functional programming, and Haskell in particular. See [The Haskell Connection](#) for some suggestions.

11.6.7 Errors

Above, you've learnt about `assertMsg` and `abort`, which represent (potentially) failing actions. Actions only have an effect when they are performed, so the following script succeeds or fails depending on the value of `abortScript`:

```
nonPerformedAbort = do
  let abortScript = False
  let failingAction : Script () = abort "Foo"
  let successfulAction : Script () = return ()
  if abortScript then failingAction else successfulAction
```

However, what about errors in contexts other than actions? Suppose we wanted to implement a function `pow` that takes an integer to the power of another positive integer. How do we handle that the second parameter has to be positive?

One option is to make the function explicitly partial by returning an `Optional`:

```
optPow : Int -> Int -> Optional Int
optPow base exponent
| exponent == 0 = Some 1
| exponent > 0 =
  let Some result = optPow base (exponent - 1)
  in Some (base * result)
| otherwise = None
```

This is a useful pattern if we need to be able to handle the error case, but it also forces us to always handle it as we need to extract the result from an `Optional`. We can see the impact on convenience in the definition of the above function. In cases, like division by zero or the above function, it can therefore be preferable to fail catastrophically instead:

```
errPow : Int -> Int -> Int
errPow base exponent
| exponent == 0 = 1
| exponent > 0 = base * errPow base (exponent - 1)
| otherwise = error "Negative exponent not supported"
```

The big downside to this is that even unused errors cause failures. The following script will fail, because `failingComputation` is evaluated:

```
nonPerformedError = script do
  let causeError = False
  let failingComputation = errPow 1 (-1)
  let successfulComputation = errPow 1 1
  return if causeError then failingComputation else successfulComputation
```

`error` should therefore only be used in cases where the error case is unlikely to be encountered, and where explicit partiality would unduly impact usability of the function.

11.6.8 Next Up

You can now specify a precise data and data-transformation model for Daml ledgers. In [Parties and Authority](#), you will learn how to properly involve multiple parties in contracts, how authority works in Daml, and how to build contract models with strong guarantees in contexts with mutually distrusting entities.

11.7 Parties and Authority

Daml is designed for distributed applications involving mutually distrusting parties. In a well-constructed contract model, all parties have strong guarantees that nobody cheats or circumvents the rules laid out by templates and choices.

In this section you will learn about Daml's authorization rules and how to develop contract models that give all parties the required guarantees. In particular, you'll learn how to:

- Pass authority from one contract to another
- Write advanced choices
- Reason through Daml's Authorization model

Hint: Remember that you can load all the code for this section into a folder called `intro6` by running `daml new intro6 --template daml-intro-6`

11.7.1 Preventing IOU Revocation

The `SimpleIou` contract from [Transform Data Using Choices](#) and [Add Constraints to a Contract](#) has one major problem: The contract is only signed by the `issuer`. The signatories are the parties with the power to create and archive contracts. If Alice gave Bob a `SimpleIou` for \$100 in exchange for some goods, she could just archive it after receiving the goods. Bob would have a record of such actions, but would have to resort to off-ledger means to get his money back:

```
template SimpleIou
with
  issuer : Party
  owner  : Party
  cash   : Cash
where
  signatory issuer
```

```
simple_iou_test = do
  alice <- allocateParty "Alice"
  bob   <- allocateParty "Bob"

  -- Alice and Bob enter into a trade.
  -- Alice transfers the payment as a SimpleIou.
  iou <- submit alice do
    createCmd SimpleIou with
      issuer = alice
      owner  = bob
      cash   = Cash with
```

(continues on next page)

(continued from previous page)

```

    amount = 100.0
    currency = "USD"

    passTime (days 1)
    -- Bob delivers the goods.

    passTime (minutes 10)
    -- Alice just deletes the payment.
    submit alice do
      archiveCmd iou

```

For a party to have any guarantees that only those transformations specified in the choices are actually followed, they either need to be a signatory themselves, or trust one of the signatories to not agree to transactions that archive and re-create contracts in unexpected ways. To make the `SimpleIou` safe for Bob, you need to add him as a signatory:

```

template Iou
  with
    issuer : Party
    owner  : Party
    cash   : Cash
  where
    signatory issuer, owner

    choice Transfer
      : ContractId Iou
      with
        newOwner : Party
      controller owner
      do
        assertMsg "newOwner cannot be equal to owner." (owner /= newOwner)
        create this with
          owner = newOwner

```

There's a new problem here: There is no way for Alice to issue or transfer this `Iou` to Bob. To get an `Iou` with Bob's signature as owner onto the ledger, his authority is needed:

```

iou_test = do
  alice <- allocateParty "Alice"
  bob   <- allocateParty "Bob"

  -- Alice and Bob enter into a trade.
  -- Alice wants to give Bob an Iou, but she can't without Bob's authority.
  submitMustFail alice do
    createCmd Iou with
      issuer = alice
      owner  = bob
      cash   = Cash with
        amount = 100.0
        currency = "USD"

  -- She can issue herself an Iou.
  iou <- submit alice do
    createCmd Iou with
      issuer = alice

```

(continues on next page)

(continued from previous page)

```

owner = alice
cash = Cash with
  amount = 100.0
  currency = "USD"

-- However, she can't transfer it to Bob.
submitMustFail alice do
  exerciseCmd iou Transfer with
    newOwner = bob

```

This may seem awkward, but notice that the `ensure` clause is gone from the `Iou` again. The above `Iou` can contain negative values so Bob should be glad that Alice cannot put his signature on any `Iou`.

You'll now learn a couple of common ways of building issuance and transfer workflows for the above `Iou`, before diving into the authorization model in full.

11.7.2 Use Propose-Accept Workflows for One-Off Authorization

If there is no standing relationship between Alice and Bob, Alice can propose the issuance of an `Iou` to Bob, giving him the choice to accept. You can do so by introducing a proposal contract `IouProposal`:

```

template IouProposal
  with
    iou : Iou
  where
    signatory iou.issuer
    observer iou.owner

    choice IouProposal_Accept
      : ContractId Iou
      controller iou.owner
      do
        create iou

```

Note how we have used the fact that templates are records here to store the `Iou` in a single field:

```

iouProposal <- submit alice do
  createCmd IouProposal with
    iou = Iou with
      issuer = alice
      owner = bob
      cash = Cash with
        amount = 100.0
        currency = "USD"

submit bob do
  exerciseCmd iouProposal IouProposal_Accept

```

The `IouProposal` contract carries the authority of `iou.issuer` by virtue of them being a signatory. By exercising the `IouProposal_Accept` choice, Bob adds his authority to that of Alice, which is why an `Iou` with both signatories can be created in the context of that choice.

The choice is called `IouProposal_Accept`, not `Accept`, because propose-accept patterns are very common. In fact, you'll see another one just below. As each choice defines a record type, you cannot

have two choices of the same name in scope. It's a good idea to qualify choice names to ensure uniqueness.

The above solves issuance, but not transfers. You can solve transfers exactly the same way, though, by creating a `TransferProposal`:

```
template IouTransferProposal
  with
    iou : Iou
    newOwner : Party
  where
    signatory (signatory iou)
    observer (observer iou), newOwner

    choice IouTransferProposal_Cancel
      : ContractId Iou
      controller iou.owner
      do
        create iou

    choice IouTransferProposal_Reject
      : ContractId Iou
      controller newOwner
      do
        create iou

    choice IouTransferProposal_Accept
      : ContractId Iou
      controller newOwner
      do
        create iou with
          owner = newOwner
```

In addition to defining the signatories of a contract, `signatory` can also be used to extract the signatories from another contract. Instead of writing `signatory (signatory iou)`, you could write `signatory iou.issuer, iou.owner`.

The `IouProposal` had a single signatory so it could be cancelled easily by archiving it. Without a `Cancel` choice, the `newOwner` could abuse an open `TransferProposal` as an option. The triple `Accept`, `Reject`, `Cancel` is common to most proposal templates.

To allow an `iou.owner` to create such a proposal, you need to give them the choice to propose a transfer on the `Iou` contract. The choice looks just like the above `Transfer` choice, except that a `IouTransferProposal` is created instead of an `Iou`:

```
choice ProposeTransfer
  : ContractId IouTransferProposal
  with
    newOwner : Party
  controller owner
  do
    assertMsg "newOwner cannot be equal to owner." (owner /= newOwner)
    create IouTransferProposal with
      iou = this
      newOwner
```

Bob can now transfer his `Iou`. The transfer workflow can even be used for issuance:

```

charlie <- allocateParty "Charlie"

-- Alice issues an Iou using a transfer proposal.
tpab <- submit alice do
  createCmd IouTransferProposal with
    newOwner = bob
    iou = Iou with
      issuer = alice
      owner = alice
      cash = Cash with
        amount = 100.0
        currency = "USD"

-- Bob accepts the transfer from Alice.
iou2 <- submit bob do
  exerciseCmd tpab IouTransferProposal_Accept

-- Bob offers Charlie a transfer.
tpbc <- submit bob do
  exerciseCmd iou2 ProposeTransfer with
    newOwner = charlie

-- Charlie accepts the transfer from Bob.
submit charlie do
  exerciseCmd tpbc IouTransferProposal_Accept

```

11.7.3 Use Role Contracts for Ongoing Authorization

Many actions, like the issuance of assets or their transfer, can be pre-agreed. You can represent this succinctly in Daml through relationship or role contracts.

Jointly, an owner and newOwner can transfer an asset, as demonstrated in the script above. In [Composing Choices](#), you will see how to compose the `ProposeTransfer` and `IouTransferProposal_Accept` choices into a single new choice, but for now, here is a different way. You can give them the joint right to transfer an IOU:

```

choice Mutual_Transfer
  : ContractId Iou
  with
    newOwner : Party
  controller owner, newOwner
  do
    create this with
      owner = newOwner

```

Up to now, the controllers of choices were known from the current contract. Here, the `newOwner` variable is part of the choice arguments, not the `Iou`.

This is also the first time we have shown a choice with more than one controller. If multiple controllers are specified, the authority of *all* the controllers is needed. Here, neither `owner`, nor `newOwner` can execute a transfer unilaterally, hence the name `Mutual_Transfer`.

```

template IouSender
  with

```

(continues on next page)

(continued from previous page)

```

sender : Party
receiver : Party
where
  signatory receiver
  observer sender

  nonconsuming choice Send_Iou
    : ContractId Iou
  with
    iouCid : ContractId Iou
  controller sender
  do
    iou <- fetch iouCid
    assert (iou.cash.amount > 0.0)
    assert (sender == iou.owner)
    exercise iouCid Mutual_Transfer with
      newOwner = receiver

```

The above `IouSender` contract now gives one party, the `sender` the right to send `Iou` contracts with positive amounts to a receiver. The `nonconsuming` keyword on the choice `Send_Iou` changes the behaviour of the choice so that the contract it's exercised on does not get archived when the choice is exercised. That way the `sender` can use the contract to send multiple `Ious`.

Here it is in action:

```

-- Bob allows Alice to send him Ious.
sab <- submit bob do
  createCmd IouSender with
    sender = alice
    receiver = bob

-- Charlie allows Bob to send him Ious.
sbc <- submit charlie do
  createCmd IouSender with
    sender = bob
    receiver = charlie

-- Alice can now send the Iou she issued herself earlier.
iou4 <- submit alice do
  exerciseCmd sab Send_Iou with
    iouCid = iou

-- Bob sends it on to Charlie.
submit bob do
  exerciseCmd sbc Send_Iou with
    iouCid = iou4

```

11.7.4 Daml's Authorization Model

Hopefully, the above will have given you a good intuition for how authority is passed around in Daml. In this section you'll learn about the formal authorization model to allow you to reason through your contract models. This will allow you to construct them in such a way that you don't run into authorization errors at runtime, or, worse still, allow malicious transactions.

In [Choices In the Ledger Model](#) you learned that a transaction is, equivalently, a tree of transactions, or a forest of actions, where each transaction is a list of actions, and each action has a child-transaction called its consequences.

Each action has a set of *required authorizers* – the parties that must authorize that action – and each transaction has a set of *authorizers* – the parties that did actually authorize the transaction.

The authorization rule is that the required authorizers of every action are a subset of the authorizers of the parent transaction.

The required authorizers of actions are:

- The required authorizers of an **exercise action** are the controllers on the corresponding choice. Remember that `Archive` and `archive` are just an implicit choice with the signatories as controllers.

- The required authorizers of a **create action** are the signatories of the contract.

- The required authorizers of a **fetch action** (which also includes `fetchByKey`) are somewhat dynamic and covered later.

The authorizers of transactions are:

- The root transaction of a commit is authorized by the submitting party.

- The consequences of an exercise action are authorized by the actors of that action plus the signatories of the contract on which the action was taken.

11.7.4.1 An Authorization Example

Consider the transaction from the script above where Bob sends an `Iou` to Charlie using a `Send_Iou` contract. It is authorized as follows, ignoring fetches:

- Bob submits the transaction so he's the authorizer on the root transaction.

- The root transaction has a single action, which is to exercise `Send_Iou` on a `IouSender` contract with Bob as `sender` and Charlie as `receiver`. Since the controller of that choice is the `sender`, Bob is the required authorizer.

- The consequences of the `Send_Iou` action are authorized by its actors, Bob, as well as signatories of the contract on which the action was taken. That's Charlie in this case, so the consequences are authorized by both Bob and Charlie.

- The consequences contain a single action, which is a `Mutual_Transfer` with Charlie as `newOwner` on an `Iou` with `issuer` Alice and `owner` Bob. The required authorizers of the action are the `owner`, Bob, and the `newOwner`, Charlie, which matches the parent's authorizers.

- The consequences of `Mutual_Transfer` are authorized by the actors (Bob and Charlie), as well as the signatories on the `Iou` (Alice and Bob).

- The single action on the consequences, the creation of an `Iou` with `issuer` Alice and `owner` Charlie has required authorizers Alice and Charlie, which is a proper subset of the parent's authorizers.

You can see the graph of this transaction in the transaction view of the IDE:

```

TX 12 1970-01-01T00:00:00Z (Parties:276:3)
#12:0
└─ disclosed to (since): 'Bob' (12), 'Charlie' (12)
└─> 'Bob' exercises Send_Iou on #10:0 (Parties:IouSender)
    with
        iouCid = #11:3
children:
#12:1
└─ disclosed to (since): 'Bob' (12), 'Charlie' (12), 'Alice' (12)
└─> 'Alice' and 'Bob' fetch #11:3 (Parties:Iou)

#12:2
└─ disclosed to (since): 'Bob' (12), 'Charlie' (12), 'Alice' (12)
└─> 'Bob' and 'Charlie' exercise Mutual_Transfer on #11:3 (Parties:Iou)
    with
        newOwner = 'Charlie'

children:
#12:3
└─ disclosed to (since): 'Bob' (12), 'Charlie' (12), 'Alice' (12)
└─> 'Alice' and 'Charlie' create Parties:Iou
    with
        issuer = 'Alice';
        owner = 'Charlie';
        cash =
            (Parties:Cash with
                currency = "USD"; amount = 100.0000000000)

```

Note that authority is not automatically transferred transitively.

```

template NonTransitive
with
    partyA : Party
    partyB : Party
where
    signatory partyA
    observer partyB

    choice TryA
        : ContractId NonTransitive
        controller partyA
        do
            create NonTransitive with
                partyA = partyB
                partyB = partyA

    choice TryB
        : ContractId NonTransitive
        with
            other : ContractId NonTransitive
        controller partyB
        do
            exercise other TryA

```

```

ntl <- submit alice do
    createCmd NonTransitive with
        partyA = alice

```

(continues on next page)

(continued from previous page)

```
partyB = bob
nt2 <- submit alice do
  createCmd NonTransitive with
    partyA = alice
    partyB = bob

submitMustFail bob do
  exerciseCmd ntl TryB with
    other = nt2
```

The consequences of `TryB` are authorized by both Alice and Bob, but the action `TryA` only has Alice as an actor and Alice is the only signatory on the contract.

Therefore, the consequences of `TryA` are only authorized by Alice. Bob's authority is now missing to create the flipped `NonTransitive` so the transaction fails.

11.7.5 Next Up

In [Composing Choices](#) you will put everything you have learned together to build a simple asset holding and trading model akin to that in the [IOU Quickstart Tutorial](#). In that context you'll learn a bit more about the `Update` action and how to use it to compose transactions, as well as about privacy on Daml ledgers.

11.8 Composing Choices

It's time to put everything you've learned so far together into a complete and secure Daml model for asset issuance, management, transfer, and trading. This application will have capabilities similar to the one in [IOU Quickstart Tutorial](#). In the process you will learn about a few more concepts:

- Daml projects, packages and modules
- Composition of transactions
- Observers and stakeholders
- Daml's execution model
- Privacy

The model in this section is not a single Daml file, but a Daml project consisting of several files that depend on each other.

Hint: Remember that you can load all the code for this section into a folder called `intro7` by running `daml new intro7 --template daml-intro-7`

11.8.1 Daml Projects

Daml is organized in projects, packages and modules. A Daml project is specified using a single `daml.yaml` file, and compiles into a package in Daml's intermediate language, or bytecode equivalent, Daml-LF. Each Daml file within a project becomes a Daml module, which is a bit like a namespace. Each Daml project has a source root specified in the `source` parameter in the project's `daml.yaml` file. The package will include all modules specified in `*.daml` files beneath that source directory.

You can start a new project with a skeleton structure using `daml new project-name` in the terminal. A minimal project would contain just a `daml.yaml` file and an empty directory of source files.

Take a look at the `daml.yaml` for the this chapter's project:

```

sdk-version: __VERSION__
name: __PROJECT_NAME__
source: daml
version: 1.0.0
dependencies:
  - daml-prim
  - daml-stdlib
  - daml-script

```

You can generally set `name` and `version` freely to describe your project. `dependencies` does what the name suggests: It includes dependencies. You should always include `daml-prim` and `daml-stdlib`. The former contains internals of compiler and Daml Runtime, the latter gives access to the Daml Standard Library. `daml-script` contains the types and standard library for Daml Script.

You compile a Daml project by running `daml build` from the project root directory. This creates a `dar` file in `.daml/dist/dist/${project_name}-${project_version}.dar`. A `dar` file is Daml's equivalent of a `JAR` file in Java: it's the artifact that gets deployed to a ledger to load the package and its dependencies. `dar` files are fully self-contained in that they contain all dependencies of the main package. More on all of this in [Work with Dependencies](#).

11.8.2 Project Structure

This project contains an asset holding model for transferable, fungible assets and a separate trade workflow. The templates are structured in three modules: `Intro.Asset`, `Intro.Asset.Role`, and `Intro.Asset.Trade`.

In addition, there are tests in modules `Test.Intro.Asset`, `Test.Intro.Asset.Role`, and `Test.Intro.Asset.Trade`.

All but the last `.`-separated segment in module names correspond to paths relative to the project source directory, and the last one to a file name. The folder structure therefore looks like this:

```

.
├── daml
│   └── Intro
│       ├── Asset
│       │   ├── Role.daml
│       │   └── Trade.daml
│       └── Asset.daml

```

(continues on next page)

(continued from previous page)

Each file contains a module header. For example, `daml/Intro/Asset/Role.daml`:

```
module Intro.Asset.Role where
```

You can import one module into another using the `import` keyword. The `LibraryModules` module imports all six modules:

```
import Intro.Asset
```

Imports always have to appear just below the module declaration. You can optionally add a list of names after the import to import only the selected names:

```
import DA.List (sortOn, groupOn)
```

If your module contains any Daml Scripts, you need to import the corresponding functionality:

```
import Daml.Script
```

11.8.3 Project Overview

The project both changes and adds to the `Iou` model presented in [Parties and Authority](#):

Assets are fungible in the sense that they have `Merge` and `Split` choices that allow the owner to manage their holdings.

Transfer proposals now need the authorities of both `issuer` and `newOwner` to accept. This makes `Asset` safer than `Iou` from the issuer's point of view.

With the `Iou` model, an `issuer` could end up owing cash to anyone as transfers were authorized by just `owner` and `newOwner`. In this project, only parties having an `AssetHolder` contract can end up owning assets. This allows the `issuer` to determine which parties may own their assets.

The `Trade` template adds a swap of two assets to the model.

11.8.4 Composed Choices and Scripts

This project showcases how you can put the `Update` and `Script` actions you learned about in [Parties and Authority](#) to good use. For example, the `Merge` and `Split` choices each perform several actions in their consequences.

Two create actions in case of `Split`

One create and one archive action in case of `Merge`

```

choice Split
  : SplitResult
  with
    splitQuantity : Decimal
  controller owner
  do
    splitAsset <- create this with
      quantity = splitQuantity
    remainder <- create this with
      quantity = quantity - splitQuantity
    return SplitResult with
      splitAsset
      remainder

choice Merge
  : ContractId Asset
  with
    otherCid : ContractId Asset
  controller owner
  do
    other <- fetch otherCid
    assertMsg
      "Merge failed: issuer does not match"
      (issuer == other.issuer)
    assertMsg
      "Merge failed: owner does not match"
      (owner == other.owner)
    assertMsg
      "Merge failed: symbol does not match"
      (symbol == other.symbol)
    archive otherCid
    create this with
      quantity = quantity + other.quantity

```

The `return` function used in `Split` is available in any `Action` context. The result of `return x` is a no-op containing the value `x`. It has an alias `pure`, indicating that it's a pure value, as opposed to a value with side-effects. The `return` name makes sense when it's used as the last statement in a `do` block as its argument is indeed the `return` -value of the `do` block in that case.

Taking transaction composition a step further, the `Trade_Settle` choice on `Trade` composes two exercise actions:

```

choice Trade_Settle
  : (ContractId Asset, ContractId Asset)
  with
    quoteAssetCid : ContractId Asset
    baseApprovalCid : ContractId TransferApproval
  controller quoteAsset.owner
  do
    fetchedBaseAsset <- fetch baseAssetCid
    assertMsg
      "Base asset mismatch"
      (baseAsset == fetchedBaseAsset with
        observers = baseAsset.observers)

    fetchedQuoteAsset <- fetch quoteAssetCid

```

(continues on next page)

(continued from previous page)

```

assertMsg
  "Quote asset mismatch"
  (quoteAsset == fetchedQuoteAsset with
    observers = quoteAsset.observers)

transferredBaseCid <- exercise
  baseApprovalCid TransferApproval_Transfer with
    assetCid = baseAssetCid

transferredQuoteCid <- exercise
  quoteApprovalCid TransferApproval_Transfer with
    assetCid = quoteAssetCid

return (transferredBaseCid, transferredQuoteCid)

```

The resulting transaction, with its two nested levels of consequences, can be seen in the `test_trade` script in `Test.Intro.Asset.Trade`:

```

TX 14 1970-01-01T00:00:00Z (Test.Intro.Asset.Trade:79:23)
#14:0
└─ disclosed to (since): 'Alice' (14), 'Bob' (14)

        #14:6
        └─ disclosed to (since): 'Alice' (14), 'Bob' (14), 'USD_Bank' (14)
        └─> 'Bob' and 'USD_Bank' create Intro.Asset:Asset
            with
              issuer = 'USD_Bank';
              owner = 'Bob';
              symbol = "USD";

```

(continues on next page)

(continued from previous page)

```

                                quantity = 100.0000000000;
                                observers = []

#14:7
|   disclosed to (since): 'Alice' (14), 'Bob' (14), 'EUR_Bank' (14)
|   ↳ 'Alice',
|   'Bob' exercises TransferApproval_Transfer on #11:1 (Intro.
↳ Asset:TransferApproval)
    with
        assetCid = #9:1
    children:
#14:8
|   disclosed to (since): 'Alice' (14), 'Bob' (14), 'EUR_Bank' (14)
|   ↳ 'Bob' and 'EUR_Bank' fetch #9:1 (Intro.Asset:Asset)

#14:9
|   disclosed to (since): 'Alice' (14), 'Bob' (14), 'EUR_Bank' (14)
|   ↳ 'Bob' and 'EUR_Bank' exercise Archive on #9:1 (Intro.Asset:Asset)

#14:10
|   disclosed to (since): 'Alice' (14), 'Bob' (14), 'EUR_Bank' (14)
|   ↳ 'Alice' and 'EUR_Bank' create Intro.Asset:Asset
    with
        issuer = 'EUR_Bank';
        owner = 'Alice';
        symbol = "EUR";
        quantity = 90.0000000000;
        observers = []

```

Similar to choices, you can see how the scripts in this project are built up from each other:

```

test_issuance = do
  setupResult@(alice, bob, bank, aha, ahb) <- setupRoles

  assetCid <- submit bank do
    exerciseCmd aha Issue_Asset
    with
      symbol = "USD"
      quantity = 100.0

  Some asset <- queryContractId bank assetCid
  assert (asset == Asset with
    issuer = bank
    owner = alice
    symbol = "USD"
    quantity = 100.0
    observers = []
  )

  return (setupResult, assetCid)

```

In the above, the `test_issuance` script in `Test.Intro.Asset.Role` uses the output of the `setupRoles` script in the same module.

The same line shows a new kind of pattern matching. Rather than writing `setupResult <- setupRoles` and then accessing the components of `setupResult` using `_1`, `_2`, etc., you can give

them names. It's equivalent to writing:

```
setupResult <- setupRoles
case setupResult of
  (alice, bob, bank, aha, ahb) -> ...
```

Just writing `(alice, bob, bank, aha, ahb) <- setupRoles` would also be legal, but `setupResult` is used in the return value of `test_issuance` so it makes sense to give it a name, too. The notation with `@` allows you to give both the whole value as well as its constituents names in one go.

11.8.5 Daml's Execution Model

Daml's execution model is fairly easy to understand, but has some important consequences. You can imagine the life of a transaction as follows:

Command Submission A user submits a list of Commands via the Ledger API of a Participant Node, acting as a Party hosted on that Node. That party is called the requester.

Interpretation Each Command corresponds to one or more Actions. During this step, the Update corresponding to each Action is evaluated in the context of the ledger to calculate all consequences, including transitive ones (consequences of consequences, etc.). The result of this is a complete Transaction. Together with its requestor, this is also known as a Commit.

Blinding On ledgers with strong privacy, projections (see [Privacy](#)) for all involved parties are created. This is also called *projecting*.

Transaction Submission The Transaction/Commit is submitted to the network.

Validation The Transaction/Commit is validated by the network. Who exactly validates can differ from implementation to implementation. Validation also involves scheduling and collision detection, ensuring that the transaction has a well-defined place in the (partial) ordering of Commits, and no double spends occur.

Commitment The Commit is actually committed according to the commit or consensus protocol of the Ledger.

Confirmation The network sends confirmations of the commitment back to all involved Participant Nodes.

Completion The user gets back a confirmation through the Ledger API of the submitting Participant Node.

The first important consequence of the above is that all transactions are committed atomically. Either a transaction is committed as a whole and for all participants, or it fails.

That's important in the context of the `Trade_Settle` choice shown above. The choice transfers a `baseAsset` one way and a `quoteAsset` the other way. Thanks to transaction atomicity, there is no chance that either party is left out of pocket.

The second consequence is that the requester of a transaction knows all consequences of their submitted transaction – there are no surprises in Daml. However, it also means that the requester must have all the information to interpret the transaction. We also refer to this as Principle 2 a bit later on this page.

That's also important in the context of `Trade`. In order to allow Bob to interpret a transaction that transfers Alice's cash to Bob, Bob needs to know both about Alice's `Asset` contract, as well as about some way for Alice to accept a transfer – remember, accepting a transfer needs the authority of `issuer` in this example.

11.8.6 Observers

Observers are Daml's mechanism to disclose contracts to other parties. They are declared just like signatories, but using the `observer` keyword, as shown in the `Asset` template:

```
template Asset
  with
    issuer : Party
    owner  : Party
    symbol : Text
    quantity : Decimal
    observers : [Party]
  where
    signatory issuer, owner
    ensure quantity > 0.0

    observer observers
```

The `Asset` template also gives the `owner` a choice to set the observers, and you can see how Alice uses it to show her `Asset` to Bob just before proposing the trade. You can try out what happens if she didn't do that by removing that transaction:

```
usdCid <- submit alice do
  exerciseCmd usdCid SetObservers with
    newObservers = [bob]
```

Observers have guarantees in Daml. In particular, they are guaranteed to see actions that create and archive the contract on which they are an observer.

Since observers are calculated from the arguments of the contract, they always know about each other. That's why, rather than adding Bob as an observer on Alice's `AssetHolder` contract, and using that to authorize the transfer in `Trade_Settle`, Alice creates a one-time authorization in the form of a `TransferAuthorization`. If Alice had lots of counterparties, she would otherwise end up leaking them to each other.

Choice controllers are not automatically made observers, as they can only be calculated at the point in time when the choice arguments are known.

11.8.7 Privacy

Daml's privacy model is based on two principles:

Principle 1. Parties see those actions that they have a stake in. Principle 2. Every party that sees an action sees its (transitive) consequences.

Principle 2 is necessary to ensure that every party can independently verify the validity of every transaction they see.

A party has a stake in an action if

- they are a required authorizer of it
- they are a signatory of the contract on which the action is performed
- they are an observer on the contract, and the action creates or archives it

What does that mean for the `exercise tradeCid Trade_Settle` action from `test_trade`?

Alice is the signatory of `tradeCid` and Bob a required authorizer of the `Trade_Settled` action, so both of them see it. According to principle 2 above, that means they get to see everything in the transaction.

The consequences contain, next to some `fetch` actions, two `exercise` actions of the choice `TransferApproval_Transfer`.

Each of the two involved `TransferApproval` contracts is signed by a different `issuer`, which see the action on their contract. So the `EUR_Bank` sees the `TransferApproval_Transfer` action for the `EUR Asset` and the `USD_Bank` sees the `TransferApproval_Transfer` action for the `USD Asset`.

Some Daml ledgers, like the script runner and the Sandbox, work on the principle of `data minimization`, meaning nothing more than the above information is distributed. That is, the `projection` of the overall transaction that gets distributed to `EUR_Bank` in step 4 of [Daml's Execution Model](#) would consist only of the `TransferApproval_Transfer` and its consequences.

Other implementations, in particular those on public blockchains, may have weaker privacy constraints.

11.8.7.1 Divulgence

Note that principle 2 of the privacy model means that sometimes parties see contracts that they are not signatories or observers on. If you look at the final ledger state of the `test_trade` script, for example, you may notice that both Alice and Bob now see both assets, as indicated by the Xs in their respective columns:

Intro.Asset:Asset										
Alice	Bob	EUR_Bank	USD_Bank	id	status	issuer	owner	symbol	quantity	observers
X	X	-	X	#15:6	active	'USD_Bank'	'Bob'	"USD"	100.0	[]
X	X	X	-	#15:10	active	'EUR_Bank'	'Alice'	"EUR"	90.0	[]

This is because the `create` action of these contracts are in the transitive consequences of the `Trade_Settle` action both of them have a stake in. This kind of disclosure is often called `divulgence` and needs to be considered when designing Daml models for privacy sensitive applications.

11.8.8 Next Up

In [Exception Handling](#), we will learn about how errors in your model can be handled in Daml.

11.9 Daml Interfaces

After defining a few templates in Daml, you've probably found yourself repeating some behaviors between them. For instance, many templates have a notion of ownership where a party is designated as the `owner` of the contract, and this party has the power to transfer ownership of the contract to a different party (subject to that party agreeing to the transfer!). Daml Interfaces provide a way to abstract those behaviors into a Daml type.

Hint: Remember that you can load all the code for this section into a folder called `intro13` by running `daml new intro13 --template daml-intro-13`

11.9.1 Context

First, define some templates:

```
template Cash
  with
    issuer : Party
    owner  : Party
    currency : Text
    amount : Decimal
  where
    signatory issuer, owner
    ensure amount > 0.0

    choice ProposeCashTransfer : ContractId CashTransferProposal
      with newOwner : Party
      controller owner
      do
        create CashTransferProposal with
          cash = this
          newOwner = newOwner
```

```
template CashTransferProposal
  with
    cash : Cash
    newOwner : Party
  where
    signatory (signatory cash)
    observer newOwner

    choice AcceptCashTransferProposal : ContractId Cash
      controller newOwner
      do
        create cash with
          owner = newOwner

    -- Note that RejectCashTransferProposal and WithdrawCashTransferProposal are
    -- almost identical except for the controller - the "recipient" (the new
    -- owner) can reject the proposal, while the "sender" (the old owner) can
    -- withdraw the proposal if the recipient hasn't accepted it already. The
    -- effect in either case is the same: the CashTransferProposal contract is
```

(continues on next page)

(continued from previous page)

```
-- archived and a new Cash contract is created with the same contents as the
-- original, but with a new ContractId on the ledger.
choice RejectCashTransferProposal : ContractId Cash
  controller newOwner
  do
    create cash

choice WithdrawCashTransferProposal : ContractId Cash
  controller cash.owner
  do
    create cash
```

These declarations from `intro13/daml/Cash.daml` define `Cash` as a simple template with an issuer, an owner, a currency, and an amount. A `Cash` contract grants its owner the choice `ProposeCashTransfer`, which allows the owner to propose another party, the `newOwner`, to take over ownership of the asset.

This is mediated by the `CashTransferProposal` template, which grants two choices to the new owner: `AcceptCashTransferProposal` and `RejectCashTransferProposal`, each of which archives the `CashTransferProposal` and creates a new `Cash` contract; in the former case the owner of the new `Cash` will be `newOwner`, in the latter, it will be the existing owner. Finally, the existing owner also has the choice `WithdrawCashTransferProposal`, which archives the proposal and creates a new `Cash` contract with identical contents to the original one.

Overall, the effect is that a `Cash` contract can be transferred to another party, if they agree, in two steps.

The declarations from `intro13/daml/NFT.daml` declare the templates `NFT` and `NFTTransferProposal` following the same pattern, with names changed where appropriate, with the main difference being that an `NFT` has a `url : Text` field whereas `Cash` has `currency : Text` and `amount : Decimal`.

11.9.2 Interface Definition

To abstract this behavior, you will next introduce two interfaces: `IAsset` and `IAssetTransferProposal`.

Hint: It is not mandatory to prefix interface names with the letter `I`, but it can be convenient to tell at a glance whether or not a type is an interface.

```
interface IAsset
  where
    viewtype VAsset

  setOwner : Party -> IAsset
  toTransferProposal : Party -> IAssetTransferProposal

  choice ProposeIAssetTransfer : ContractId IAssetTransferProposal
    with newOwner : Party
    controller (view this).owner
    do
      create (toTransferProposal this newOwner)
```

```

interface IAssetTransferProposal
  where
    viewtype VAssetTransferProposal

  asset : IAsset

  choice AcceptIAssetTransferProposal : ContractId IAsset
    controller (view this).newOwner
    do
      create $ setOwner (asset this) (view this).newOwner

  choice RejectIAssetTransferProposal : ContractId IAsset
    controller (view this).newOwner
    do
      create (asset this)

  choice WithdrawIAssetTransferProposal : ContractId IAsset
    controller (view (asset this)).owner
    do
      create (asset this)

```

There are a few things happening here:

1. For each interface, you have defined a `viewtype`. This is mandatory for all interfaces. All viewtypes must be serializable records. The viewtype abstracts the read side by providing a uniform way in which implementations of `IAsset` are represented on the Ledger API. This declaration means that the special `view` method, when applied to a value of this interface, will return the specified type (in this case `VAsset`). This is the definition of `VAsset`:

```

data VAsset = VAsset with
  issuer : Party
  owner  : Party
  description : Text
  deriving (Eq, Ord, Show)

```

Hint: See [Serializable Types](#) for more information on serializability requirements.

2. You have defined the methods `setOwner` and `toTransferProposal` as part of the `IAsset` interface, and method `asset` as part of the `IAssetTransferProposal` interface. Later, when you provide instances of these interfaces, you will see that it is mandatory to implement each of these methods.
3. You have defined the choice `ProposeIAssetTransfer` as part of the `IAsset` interface, and the choices `AcceptIAssetTransferProposal`, `RejectIAssetTransferProposal` and `WithdrawIAssetTransferProposal` as part of the `IAssetTransferProposal` interface. These correspond one-to-one with the choices of `Cash / CashTransferProposal` and `NFT / NFTTransferProposal`.

Notice that the choice controller and the choice body are defined in terms of the methods that you bundled with the interfaces, including the special `view` method. For example, the controller of choice `ProposeIAssetTransfer` is `(view this).owner`, that is, it's the owner field of the view for the implicit current contract `this`, in other words, the owner of the current contract. The body of this choice is `create (toTransferProposal this newOwner)`, so it creates a new contract whose contents are the result of applying the `toTransferProposal` method to the current contract and the `newOwner` field of the choice argument.

Hint: For a detailed explanation of the syntax used here, check out [Reference: Interfaces](#)

11.9.3 Interface Instances

On its own, an interface isn't very useful, since all contracts on the ledger must belong to some template type. In order to make the link between an interface and a template, you must define an interface instance inside the body of either the template or the interface. In this example, add: `interface instance IAsset for Cash` and `interface instance IAssetTransferProposal for CashTransferProposal`:

```
interface instance IAsset for Cash where
  view = VAsset with
    issuer
    owner
    description = show @Cash this

  setOwner newOwner =
    toInterface @IAsset $
      this with
        owner = newOwner

  toTransferProposal newOwner =
    toInterface @IAssetTransferProposal $
      CashTransferProposal with
        cash = this
        newOwner
```

```
interface instance IAssetTransferProposal for CashTransferProposal where
  view = VAssetTransferProposal with
    assetView = view (toInterface @IAsset cash)
    newOwner

  asset = toInterface @IAsset cash
```

The corresponding interface instances for `NFT` and `NFTTransferProposal` are very similar so we omit them here.

Inside the interface instances, you must implement every method defined for the corresponding interface, including the special `view` method. Within each method implementation the variable `this` is in scope, corresponding to the implicit current contract, which will have the type of the template (in this case `Cash` / `CashTransferProposal`), as well as each of the fields of the template type. For example, the `view` definition in `interface instance IAsset for Cash` mentions `issuer` and `owner`, which refer to the issuer and owner of the current `Cash` contract, as well as `this`, which refers to the entire `Cash` contract payload.

The implementations given for each method must match the types given in the interface definition. Notice that the `view` definition discussed above returns a `VAsset`, corresponding to `IAsset`'s `viewtype`. Similarly, `setOwner` returns an `IAsset`, and `toTransferProposal` returns an `IAssetTransferProposal`. In these last two, the function `toInterface` converts values from a template type into an interface type. In `setOwner`, `toInterface` is applied to a `Cash` value (`this with owner = newOwner`), producing an `IAsset` value; in `toTransferProposal`, it is applied

to a `CashTransferProposal` value (`CashTransferProposal` with `{...}`), producing an `IAsetTransferProposal` value.

11.9.4 Using an Interface

Now that you have some interfaces and templates with instances for them, you can reduce duplication in the code for different templates by instead going through the common interface.

For instance, both `Cash` and `NFT` are `Assets`, which means that contracts of either template have an owner who can propose to transfer the contract to a third party. Thus, you can use Daml Script (see [Test Templates Using Daml Script](#)) to test that the same contract can be created by `Alice` and successively transferred to `Bob` and then `Charlie`, who then proposes to transfer to `Dominic`, who rejects the proposal, and finally to `Emily` before withdrawing the proposal, so in the end the contract remains in `Charlie`'s ownership. This procedure is tested on the `Cash` and `NFT` templates by the Daml Script tests `cashTest` and `nftTest`, respectively, both defined in `intro13/daml/Main.daml`.

But that's a lot of duplication! `cashTest` and `nftTest` only differ in the line that creates the original asset and in the names of the choices used. With the new interfaces `IAset` and `IAsetTransferProposal`, you can write the body of this test a single time, with the name `mkAssetTest`,

```
mkAssetTest assetTxt Parties {...} mkAsset = do
```

You now have not the test itself, but rather a recipe for making the test given some inputs - in this case, `assetTxt` (a label used for debugging), `Parties {...}` (a structure containing the `Party` values for `Alice` and friends) and finally `mkAsset` (a function that returns a contract value of type `t` when given two `Party` arguments - the constraint `Implements t IAset` means that `t` must be some template with an interface instance for `IAset`).

Before looking at the body of `mkAssetTest`, notice how you use it to define the new tests `cashAssetTest` and `nftAssetTest`; these are almost identical except for the label and function given in each case to `mkAssetTest`. In effect, you have abstracted those away, so you don't need to include those details in the body of `mkAssetTest`:

```
cashAssetTest : Script (ContractId IAset)
cashAssetTest = do
  parties <- allocateParties
  mkAssetTest "Cash" parties mkCash
```

```
mkCash : Party -> Party -> Cash
mkCash issuer owner = Cash with
  issuer
  owner
  currency = "USD"
  amount = 42.0
```

```
nftAssetTest : Script (ContractId IAset)
nftAssetTest = do
  parties <- allocateParties
  mkAssetTest "NFT" parties mkNft
```

```
mkNft : Party -> Party -> NFT
mkNft issuer owner = NFT with
```

(continues on next page)

(continued from previous page)

```

issuer
owner
url = "https://nyan.feline/"

```

In turn, `mkAssetTest` isn't very different from other Daml Scripts you might have written before: it uses `do` notation as usual, including `submit` blocks constructed from `Commands` that define the ordered transactions that take place in the test. The main difference is that when querying values of interface types you cannot use the functions `query` and `queryContractId`; instead you must use `queryInterface` (for obtaining the set of visible active contracts of a given interface type) and `queryInterfaceContractId` (for obtaining a single contract given its `ContractId`). Importantly, these functions return the view of the contract corresponding to the used interface, rather than the contract record itself. This is because the ledger might contain contracts of template types that you don't know about but that do implement our interface, so the view is the only sensible thing that can be returned by the ledger.

Also note that immediately after creating the asset with `createCmd`, you convert the resulting `ContractId t` into a `ContractId IAsset` using `toInterfaceContractId`, which allows you to exercise `IAsset` choices on it.

```

mkAssetTest : forall t.
  (Template t, Implements t IAsset, HasAgreement t) =>
  Text -> Parties -> (Party -> Party -> t) -> Script (ContractId IAsset)
mkAssetTest assetTxt Parties {..} mkAsset = do
  aliceAsset <-
    alice `submit` do
      toInterfaceContractId @IAsset <$>
      createCmd (mkAsset alice alice)

  aliceAssetView <-
    queryInterfaceContractId @IAsset alice aliceAsset

  debugRaw $ unlines
    [ "Alice's Asset (" <> assetTxt <> "):"
    , "\tContractId: " <> show aliceAsset
    , "\tValue: " <> show aliceAssetView
    ]

  bobAssetTransferProposal <-
    alice `submit` do
      exerciseCmd aliceAsset ProposeIAssetTransfer with
        newOwner = bob

  bobAsset <-
    bob `submit` do
      exerciseCmd bobAssetTransferProposal AcceptIAssetTransferProposal

  charlieAssetTransferProposal <-
    bob `submit` do
      exerciseCmd bobAsset ProposeIAssetTransfer with
        newOwner = charlie

  charlieAsset <-
    charlie `submit` do
      exerciseCmd charlieAssetTransferProposal AcceptIAssetTransferProposal

```

(continues on next page)

(continued from previous page)

```

dominicAssetTransferProposal <-
  charlie `submit` do
    exerciseCmd charlieAsset ProposeIAAssetTransfer with
      newOwner = dominic

charlieAsset' <-
  dominic `submit` do
    exerciseCmd dominicAssetTransferProposal RejectIAAssetTransferProposal

emilyAssetTransferProposal <-
  charlie `submit` do
    exerciseCmd charlieAsset' ProposeIAAssetTransfer with
      newOwner = emily

charlieAsset'' <-
  charlie `submit` do
    exerciseCmd emilyAssetTransferProposal WithdrawIAAssetTransferProposal

charlieAssetView <-
  queryInterfaceContractId @IAAsset charlie charlieAsset''

debugRaw $ unlines
[ "Charlie's Asset (" <> assetTxt <> "):"
, "\tContractId: " <> show charlieAsset''
, "\tView: " <> show charlieAssetView
]

charlieAssetView ===
  Some (view (toInterface @IAAsset (mkAsset alice charlie)))

pure charlieAsset''

```

11.10 Exception Handling

The default behavior in Daml is to abort the transaction on any error and roll back all changes that have happened until then. However, this is not always appropriate. In some cases, it makes sense to recover from an error and continue the transaction instead of aborting it.

One option for doing that is to represent errors explicitly via `Either` or `Option` as shown in [Data Types](#). This approach has the advantage that it is very explicit about which operations are allowed to fail without aborting the entire transaction. However, it also has two major downsides. First, it can be invasive for operations where aborting the transaction is often the desired behavior, e.g., changing division to return `Either` or an `Option` to handle division by zero would be a very invasive change and many call sites might not want to handle the error case explicitly. Second, and more importantly, this approach does not allow rolling back ledger actions that have happened before the point where failure is detected; if a contract got created before we hit the error, there is no way to undo that except for aborting the entire transaction (which is what we were trying to avoid in the first place).

By contrast, exceptions provide a way to handle certain types of errors in such a way that, on the one hand, most of the code that is allowed to fail can be written just like normal code, and, on the other hand, the programmer can clearly delimit which part of the current transaction should be rolled back on failure. All of that still happens within the same transaction and is thereby atomic contrary

to handling the error outside of Daml.

Hint: Remember that you can load all the code for this section into a folder called `intro8` by running `daml new intro8 --template daml-intro-8`

Our example for the use of exceptions will be a simple shop template. Users can order items by calling a choice and transfer money (in the form of an `Iou` issued by their bank) from their account to the owner in return.

First, we need to setup a template to represent the account of a user:

```
template Account with
  issuer : Party
  owner  : Party
  amount : Decimal
  where
    signatory issuer, owner
    ensure amount > 0.0
    key (issuer, owner) : (Party, Party)
    maintainer key._2

    choice Transfer : () with
      newOwner : Party
      transferredAmount : Decimal
      controller owner, newOwner
      do create this with amount = amount - transferredAmount
      create Iou with issuer = issuer, owner = newOwner, amount =
        transferredAmount
      pure ()
```

Note that the template has an `ensure` clause that ensures that the amount is always positive so `Transfer` cannot transfer more money than is available.

The shop is represented as a template signed by the owner. It has a field to represent the bank accepted by the owner, a list of observers that can order items, and a fixed price for the items that can be ordered:

```
template Shop
  with
    owner : Party
    bank  : Party
    observers : [Party]
    price : Decimal
  where
    signatory owner
    observer observers
```

Note: In a real setting the price of each item for sale might be defined in a separate contract.

The ordering process is then represented by a non-consuming choice on this template which calls `Transfer` and creates an `Order` contract in return:

```

nonconsuming choice OrderItem : ContractId Order
with
  shopper : Party
controller shopper
do exerciseByKey @Account (bank, shopper) (Transfer owner price)
  create Order
    with
      shopOwner = owner
      shopper = shopper

```

However, the shop owner has realized that often orders fail because the account of their users is not topped up. They have a small trusted userbase they know well so they decide that if the account is not topped up, the shoppers can instead issue an iou to the owner and pay later. While it would be possible to check the conditions under which `Transfer` will fail in `OrderItem` this can be quite fragile: In this example, the condition is relatively simple but in larger projects replicating the conditions outside the choice and keeping the two in sync can be challenging.

Exceptions allow us to handle this differently. Rather than replicating the checks in `Transfer`, we can instead catch the exception thrown on failure. To do so we need to use a try-catch block. The `try` block defines the scope within which we want to catch exceptions while the `catch` clauses define which exceptions we want to catch and how we want to handle them. In this case, we want to catch the exception thrown by a failed `ensure` clause. This exception is defined in `daml-stdlib` as `PreconditionFailed`. Putting it together our order process for trusted users looks as follows:

```

nonconsuming choice OrderItemTrusted : ContractId Order
with
  shopper : Party
controller shopper
do cid <- create Order
  with
    shopOwner = owner
    shopper = shopper
  try do
    exerciseByKey @Account (bank, shopper) (Transfer owner price)
  catch
    PreconditionFailed _ -> do
      create Iou with
        issuer = shopper
        owner = owner
        amount = price
      pure ()
  pure cid

```

Let's walk through this code. First, as mentioned, the shop owner is the trusting kind, so he wants to start by creating the `Order` no matter what. Next, he tries to charge the customer for the order. We could, at this point, check their balance against the cost of the order, but that would amount to duplicating the logic already present in `Account`. This logic is pretty simple in this case, but duplicating invariants is a bad habit to get into. So, instead, we just try to charge the account. If that succeeds, we just merrily ignore the entire `catch` clause; if that fails, however, we do not want to destroy the `Order` contract we had already created. Instead, we want to catch the error thrown by the `ensure` clause of `Account` (in this case, it is of type `PreconditionFailed`) and try something else: create an `Iou` contract to register the debt and move on.

Note that if the `Iou` creation still failed (unlikely with our definition of `Iou` here, but could happen in more complex scenarios), because that one is not wrapped in a `try` block, we would revert to the

default Daml behaviour and the `Order` creation would be rolled back.

In addition to catching built-in exceptions like `PreconditionFailed`, you can also define your own exception types which can be caught and thrown. As an example, let's consider a variant of the `Transfer` choice that only allows for transfers up to a given limit. If the amount is higher than the limit, we throw an exception called `TransferLimitExceeded`.

We first have to define the exception and define a way to represent it as a string. In this case, our exception should store the amount that someone tried to transfer as well as the limit.

```
exception TransferLimitExceeded
  with
    limit : Decimal
    attempted : Decimal
  where
    message "Transfer of " <> show attempted <> " exceeds limit of " <> show limit
```

To throw our own exception, you can use `throw` in `Update` and `Script` or `throwPure` in other contexts.

```
choice TransferLimited : () with
  newOwner : Party
  transferredAmount : Decimal
  controller owner, newOwner
  do let limit = 50.0
    when (transferredAmount > limit) $
      throw TransferLimitExceeded with
        limit = limit
        attempted = transferredAmount
    create this with amount = amount - transferredAmount
    create Iou with issuer = issuer, owner = newOwner, amount =
      ↪transferredAmount
    pure ()
```

Finally, we can adapt our choice to catch this exception as well:

```
nonconsuming choice OrderItemTrustedLimited : ContractId Order
  with
    shopper : Party
    controller shopper
    do try do
      exerciseByKey @Account (bank, shopper) (TransferLimited owner price)
      pure ()
    catch
      PreconditionFailed _ -> do
        create Iou with
          issuer = shopper
          owner = owner
          amount = price
        pure ()
      TransferLimitExceeded _ _ -> do
        create Iou with
          issuer = shopper
          owner = owner
          amount = price
        pure ()
    create Order
```

(continues on next page)

(continued from previous page)

```
with
  shopOwner = owner
  shopper = shopper
```

For more information on exceptions, take a look at the [language reference](#).

11.10.1 Next Up

We have now seen how to develop safe models and how we can handle errors in those models in a robust and simple way. But the journey doesn't stop there. In [Work with Dependencies](#) you will learn how to extend an already running application to enhance it with new features. In that context you'll learn a bit more about the architecture of Daml, about dependencies, and about identifiers.

11.11 Work with Dependencies

The application from [Composing Choices](#) is a complete and secure model for atomic swaps of assets, but there is plenty of room for improvement. However, one can't implement all features before going live with an application so it's important to understand how to change already running code. There are fundamentally two types of change one may want to make:

1. Upgrades, which change existing logic. For example, one might want the `Asset` template to have multiple signatories.
2. Extensions, which merely add new functionality through additional templates.

Upgrades are covered in their own section outside this introduction to Daml: [Upgrading and Extending Daml Applications](#) so in this section we will extend the [Composing Choices](#) model with a simple second workflow: a multi-leg trade. In doing so, you'll learn about:

The software architecture of the Daml Stack
Dependencies and Data Dependencies
Identifiers

Since we are extending [Composing Choices](#), the setup for this chapter is slightly more complex:

1. In a base directory, load the [Composing Choices](#) project using `daml new intro7 --template daml-intro-7`. The directory `intro7` here is important as it'll be referenced by the other project we are creating.
2. In the same directory, load this chapter's project using `daml new intro9 --template daml-intro-9`.

`Dependencies` contains a new module `Intro.Asset.MultiTrade` and a corresponding test module `Test.Intro.Asset.MultiTrade`.

11.11.1 DAR, DALF, Daml-LF, and the Engine

In [Composing Choices](#) you already learnt a little about projects, Daml-LF, DAR files, and dependencies. In this chapter we will actually need to have dependencies from the current project to the [Composing Choices](#) project so it's time to learn a little more about all this.

Let's have a look inside the DAR file of [Composing Choices](#). DAR files, like Java JAR files, are just ZIP archives, but the SDK also has a utility to inspect DARs out of the box:

1. Navigate into the `intro7` directory.
2. Build using `daml build -o assets.dar`
3. Run `daml damlc inspect-dar assets.dar`

You'll get a whole lot of output. Under the header `DAR archive contains the following files:` you'll see that the DAR contains:

1. `*.dalf` files for the project and all its dependencies
2. The original Daml source code
3. `*.hi` and `*.hie` files for each `*.daml` file
4. Some meta-inf and config files

The first file is something like `intro7-1.0.0-887056cbb313b94ab9a6caf34f7fe4fbfe19cb0c861e50d1594c665567ab7625.dalf` which is the actual compiled package for the project. `*.dalf` files contain Daml-LF, which is Daml's intermediate language. The file contents are a binary encoded protobuf message from the [daml-lf schema](#). Daml-LF is evaluated on the Ledger by the Daml Engine, which is a JVM component that is part of tools like the IDE's Script runner, the Sandbox, or proper production ledgers. If Daml-LF is to Daml what Java Bytecode is to Java, the Daml Engine is to Daml what the JVM is to Java.

11.11.2 Hashes and Identifiers

Under the heading `DAR archive contains the following packages:` you get a similar looking list of package names, paired with only the long random string repeated. That hexadecimal string, `887056cbb313b94ab9a6caf34f7fe4fbfe19cb0c861e50d1594c665567ab7625` in this case, is the package hash and the primary and only identifier for a package that's guaranteed to be available and preserved. Meta information like name (`intro7`) and version (`1.0.0`) help make it human readable but should not be relied upon. You may not always get DAR files from your compiler, but be loading them from a running Ledger, or get them from an artifact repository.

We can see this in action. When a DAR file gets deployed to a ledger, not all meta information is preserved.

1. Note down your main package hash from running `inspect-dar` above
2. Start the project using `daml start`
3. Open a second terminal and run `daml ledger fetch-dar --host localhost --port 6865 --main-package-id "887056cbb313b94ab9a6caf34f7fe4fbfe19cb0c861e50d1594c665567ab7625" -o assets_ledger.dar`, making sure to replace the hash with the appropriate one.
4. Run `daml damlc inspect-dar assets_ledger.dar`

You'll notice two things. Firstly, a lot of the dependencies have lost their names, they are now only identifiable by hash. We could of course also create a second project `intro7-1.0.0` with completely different contents so even when name and version are available, package hash is the only safe identifier.

That is why over the Ledger API, all types, like templates and records are identified by the triple (entity name, module name, package hash) which refers to the version of the package that was

used to create them. Your client application should know the package hashes it wants to interact with. To aid that, `inspect-dar` also provides a machine-readable format for the information it emits: `daml damlc inspect-dar --json assets_ledger.dar`. The `main_package_id` field in the resulting JSON payload is the package hash of our project.

Starting with 2.10, client applications can interact with packages via their package name, a human-readable name defined in the `daml.yaml`. The participant guarantees that all packages referring to the same package name are backward- and forward-compatible, such that an application does not have to be upgraded every time if the package is upgraded. This functionality is only available when [smart contract upgrading \(SCU\)](#) is enabled.

In the downloaded data, observe that all the `*.daml`, `*.hi` and `*.hie` files are gone. This brings us to data dependencies.

11.11.3 Dependencies and Data Dependencies

Dependencies under the `daml.yaml` `dependencies` group rely on the `*.hi` files. The information in these files is crucial for dependencies like the Standard Library, which provide functions, types and typeclasses.

However, as you can see above, this information isn't preserved. Furthermore, preserving this information may not even be desirable. Imagine we had built `intro7` with SDK 1.100.0, and are building `intro9` with SDK 1.101.0. All the typeclasses and instances on the inbuilt types may have changed and are now present twice – once from the current SDK and once from the dependency. This gets messy fast, which is why the SDK does not support dependencies across SDK versions. For dependencies on contract models that were fetched from a ledger, or come from an older SDK version, there is a simpler kind of dependency called `data-dependencies`. The syntax for `data-dependencies` is the same, but they only rely on the binary `*.dalf` files. The name tries to confer that the main purpose of such dependencies is to handle data: Records, Choices, Templates. The stuff one needs to use contract composability across projects.

For an extension model like this one, `data-dependencies` are appropriate, so the current project includes [Composing Choices](#) that way:

```
data-dependencies:
- ../intro7/assets.dar
```

You'll notice a module `Test.Intro.Asset.TradeSetup`, which is almost a carbon copy of the [Composing Choices](#) trade setup Scripts. `data-dependencies` is designed to use existing contracts and data types. Daml Script is not imported. In practice, we also shouldn't expect that the DAR file we download from the ledger using `daml ledger fetch-dar` contains test scripts. For larger projects it's good practice to keep them separate and only deploy templates to the ledger.

11.11.4 Structuring Projects

As you've seen here, identifiers depend on the package as a whole and packages always bring all their dependencies with them. Thus changing anything in a complex dependency graph can have significant repercussions. It is therefore advisable to keep dependency graphs simple, and to separate concerns which are likely to change at different rates into separate packages.

For example, in all our projects in this intro, including this chapter, our scripts are in the same project as our templates. In practice, that means changing a test changes all identifiers, which is not desirable. It's better for maintainability to separate tests from main templates. If we had done that in [Composing Choices](#), that would also have saved us from copying [Composing Choices](#).

Similarly, we included `Trade` in the same project as `Asset` in [Composing Choices](#), even though `Trade` is a pure extension to the core `Asset` model. If we expect `Trade` to need more frequent changes, it may be a good idea to split it out into a separate project from the start.

11.11.5 Building Multiple Packages

Splitting a project into multiple independent packages, one per audience, is a common and recommended strategy. A Daml package represents an interface to a multi-party workflow, which often has different concerns for different parties. More generally, smaller interfaces are easier to use, maintain and upgrade, and can also be beneficial to improve the build times of a project. An example setup would be to split an application into `onboarding.dar`, `asset.dar`, `trading.dar` and `internal-workflows.dar`, and only share the DARs with the clients on a need-to-know basis. This allows to evolve the internal workflows quickly, without having to coordinate upgrades with the clients, who has to upload and vet any new package that you release.

Therefore, projects can be broken up into multiple packages, each with its own concerns, but managed together in a single project, which compiles the dependencies whenever necessary. This covered in the separate section [on how to build multiple packages](#).

11.11.6 Next Up

The `MultiTrade` model has more complex control flow and data handling than previous models. In [Functional Programming 101](#) you'll learn how to write more advanced logic: control flow, folds, common typeclasses, custom functions, and the Standard Library. We'll be using the same projects so don't delete your folders just yet.

11.12 Functional Programming 101

In this chapter, you will learn more about expressing complex logic in a functional language like Daml. Specifically, you'll learn about

- Function signatures and functions

- Advanced control flow (`if...else`, folds, recursion, `when`)

If you no longer have your [Composing Choices](#) and [Work with Dependencies](#) projects set up, and want to look back at the code, please follow the setup instructions in [Work with Dependencies](#) to get hold of the code for this chapter.

Note: There is a project template `daml-intro-10` for this chapter, but it only contains a single source file with the code snippets embedded in this section.

11.12.1 The Haskell Connection

The previous chapters of this introduction to Daml have mostly covered the structure of templates, and their connection to the [Daml Ledger Model](#). The logic of what happens within the `do` blocks of choices has been kept relatively simple. In this chapter, we will dive deeper into Daml's expression language, the part that allows you to write logic inside those `do` blocks. But we can only scratch the surface here. Daml borrows a lot of its language from [Haskell](#). If you want to dive deeper, or learn about specific aspects of the language you can refer to standard literature on Haskell. Some recommendations:

[Finding Success and Failure in Haskell \(Julie Maronuki, Chris Martin\)](#)
[Haskell Programming from first principles \(Christopher Allen, Julie Moronuki\)](#)
[Learn You a Haskell for Great Good! \(Miran Lipova\)](#)
[Programming in Haskell \(Graham Hutton\)](#)
[Real World Haskell \(Bryan O'Sullivan, Don Stewart, John Goerzen\)](#)

When comparing Daml to Haskell it's worth noting:

Haskell is a lazy language, which allows you to write things like `head [1..]`, meaning take the first element of an infinite list. Daml by contrast is strict. Expressions are fully evaluated, which means it is not possible to work with infinite data structures.

Daml has a `with` syntax for records and dot syntax for record field access, neither of which is present in Haskell. However, Daml supports Haskell's curly brace record notation.

Daml has a number of Haskell compiler extensions active by default.

Daml doesn't support all features of Haskell's type system. For example, there are no existential types or GADTs.

Actions are called Monads in Haskell.

11.12.2 Functions

In [Data Types](#) you learnt about one half of Daml's type system: Data types. It's now time to learn about the other, which are Function types. Function types in Daml can be spotted by looking for `->` which can be read as maps to.

For example, the function signature `Int -> Int` maps an integer to another integer. There are many such functions, but one would be:

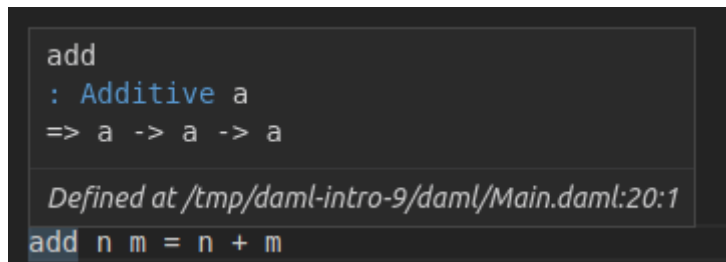

```
increment : Int -> Int
increment n = n + 1
```

You can see here that the function declaration and the function definitions are separate. The declaration can be omitted in cases where the type can be inferred by the compiler, but for top-level functions (ie ones at the same level as templates, directly under a module), it's often a good idea to include them for readability.

In the case of `increment` it could have been omitted. Similarly, we could define a function `add` without a declaration:

```
add n m = n + m
```

If you do this, and wonder what type the compiler has inferred, you can hover over the function name in the IDE:

```
add
: Additive a
=> a -> a -> a

Defined at /tmp/daml-intro-9/daml/Main.daml:20:1
add n m = n + m
```

What you see here is a slightly more complex signature:

```
add : Additive a => a -> a -> a
```

There are two interesting things going on here:

1. We have more than one `->`.
2. We have a type parameter `a` with a constraint `Additive a`.

11.12.2.1 Function Application

Let's start by looking at the right hand part `a -> a -> a`. The `->` is right associative, meaning `a -> a -> a` is equivalent to `a -> (a -> a)`. Using the `maps to` way of reading `->`, we get `a` maps to a function that maps `a` to `a`.

And this is indeed what happens. We can define a different version of `increment` by *partially applying* `add`:

```
increment2 = add 1
```

If you try this out in your IDE, you'll see that the compiler infers type `Int -> Int` again. It can do so because of the literal `1 : Int`.

So if we have a function `f : a -> b -> c -> d` and a value `valA : a`, we get `f valA : b -> c -> d`, i.e. we can apply the function argument by argument. If we also had `valB : b`, we would have `f valA valB : c -> d`. What this tells you is that function *application* is left associative: `f valA valB == (f valA) valB`.

11.12.2.2 Infix Functions

Now `add` is clearly just an alias for `+`, but what is `+`? `+` is just a function. It's only special because it starts with a symbol. Functions that start with a symbol are *infix* by default which means they can be written between two arguments. That's why we can write `1 + 2` rather than `+ 1 2`. The rules for converting between normal and infix functions are simple. Wrap an infix function in parentheses to use it as a normal function, and wrap a normal function in backticks to make it infix:

```
three = 1 `add` 2
```

With that knowledge, we could have defined `add` more succinctly as the alias that it is:

```
add2 : Additive a => a -> a -> a
add2 = (+)
```

If we want to partially apply an infix operation we can also do that as follows:

```
increment3 = (1 +)
double = (* 2)
```

Note: While function application is left associative by default, infix operators can be declared left or right associative and given a precedence. Good examples are the boolean operations `&&` and `||`, which are declared right associative with precedences 3 and 2, respectively. This allows you to write `True || True && False` and get value `True`. See section 4.4.2 of [the Haskell 98 report](#) for more on fixities.

11.12.2.3 Type Constraints

The `Additive a =>` part of the signature of `add` is a type constraint on the type parameter `a`. `Additive` here is a typeclass. You already met typeclasses like `Eq` and `Show` in [Data Types](#). The `Additive` typeclass says that you can add a thing, i.e. there is a function `(+) : a -> a -> a`. Now the way to read the full signature of `add` is: Given that `a` has an instance for the `Additive` typeclass, `a` maps to a function which maps `a` to `a`.

Typeclasses in Daml are a bit like interfaces in other languages. To be able to add two things using the `+` function, those things need to `expose` (have an instance for) the `Additive` interface (typeclass).

Unlike interfaces, typeclasses can have multiple type parameters. A good example, which also demonstrates the use of multiple constraints at the same time, is the signature of the `exercise` function:

```
exercise : (Template t, Choice t c r) => ContractId t -> c -> Update r
```

Let's turn this into prose: Given that `t` is the type of a template, and that `t` has a choice `c` with return type `r`, the `exercise` function maps a `ContractId` for a contract of type `t` to a function that takes the choice arguments of type `c` and returns an `Update` resulting in type `r`.

That's quite a mouthful, and does require one to know what *meaning* the typeclass `Choice` gives to parameters `t c` and `r`, but in many cases, that's obvious from the context or names of typeclasses and variables.

Using single letters, while common, is not mandatory. The above may be made a little bit clearer by expanding the type parameter names, at the cost of making the code a bit longer:

```
exercise : (Template template, Choice template choice result) =>
  ContractId template -> choice -> Update result
```

11.12.2.4 Pattern Matching in Arguments

You met pattern matching in [Data Types](#), using `case` expressions which is one way of pattern matching. However, it can also be convenient to do the pattern matching at the level of function arguments. Think about implementing the function `uncurry`:

```
uncurry : (a -> b -> c) -> (a, b) -> c
```

`uncurry` takes a function with two arguments (or more, since `c` could be a function), and turns it into a function from a 2-tuple to `c`. Here are three ways of implementing it, using tuple accessors, case pattern matching, and function pattern matching:

```
uncurry1 f t = f t._1 t._2

uncurry2 f t = case t of
  (x, y) -> f x y

uncurry f (x, y) = f x y
```

Any pattern matching you can do in `case` you can also do at the function level, and the compiler helpfully warns you if you did not cover all cases, which is called `non-exhaustive`.

```
fromSome : Optional a -> a
fromSome (Some x) = x
```

The above will give you a warning:

```
warning:
  Pattern match(es) are non-exhaustive
  In an equation for 'fromSome': Patterns not matched: None
```

A function that does not cover all its cases, like `fromSome` here, is called a *partial* function. `fromSome None` will cause a runtime error.

We can use function level pattern matching together with a feature called *Record Wildcards* to write the function `issueAsset` in [Work with Dependencies](#):

```
issueAsset : Asset -> Script (ContractId Asset)
issueAsset asset@(Asset with ..) = do
  assetHolders <- queryFilter @AssetHolder issuer
    (\ah -> (ah.issuer == issuer) && (ah.owner == owner))

  case assetHolders of
    (ahCid, _) :: _ -> submit asset.issuer do
      exerciseCmd ahCid Issue_Asset with ..
    [] -> abort ("No AssetHolder found for " <> show asset)
```

The `..` in the pattern match here means bind all fields from the given record to local variables, so we have local variables `issuer`, `owner`, etc.

The `..` in the second to last line means fill all fields of the new record using local variables of the matching names, in this case (per the definition of `Issue_Asset`), `symbol` and `quantity`, taken from the `asset` argument to the function. In other words, this is equivalent to:

```
exerciseCmd ahCid Issue_Asset with symbol = asset.symbol, quantity = asset.
  quantity
```

because the notation `asset@(Asset with ..)` binds `asset` to the entire record, while also binding all of the fields of `asset` to local variables.

11.12.2.5 Functions Everywhere

You have probably already guessed it: Anywhere you can put a value in Daml you can also put a function. Even inside data types:

```
data Predicate a = Predicate with
  test : a -> Bool
```

More often it makes sense to define functions locally, inside a `let` clause or similar. Good examples of this are the `validate` and `transfer` functions defined locally in the `Trade_Settle` choice of the model from [Work with Dependencies](#):

```
let
  validate (asset, assetCid) = do
    fetchedAsset <- fetch assetCid
    assertMsg
      "Asset mismatch"
      (asset == fetchedAsset with
        observers = asset.observers)

  mapA_ validate (zip baseAssets baseAssetCids)
  mapA_ validate (zip quoteAssets quoteAssetCids)

let
  transfer (assetCid, approvalCid) = do
    exercise approvalCid TransferApproval_Transfer with assetCid

  transferredBaseCids <- mapA transfer (zip baseAssetCids baseApprovalCids)
  transferredQuoteCids <- mapA transfer (zip quoteAssetCids
    ↪ quoteApprovalCids)
```

You can see that the function signature is inferred from the context here. If you look closely (or hover over the function in the IDE), you'll see that it has signature

```
validate : (HasFetch r, Eq r, HasField "observers" r a) => (r, ContractId r) ->
  ↪ Update ()
```

Note: Bear in mind that functions are not serializable, so you can't use them inside template arguments, as choice inputs, or as choice outputs. They also don't have instances of the `Eq` or `Show` typeclasses which one would commonly want on data types.

The `mapA` and `mapA_` functions loop through the lists of assets and approvals and apply the functions `validate` and `transfer` to each element of those lists, performing the resulting `Update` action in the process. We'll look at that more closely under [Looping](#) below.

11.12.2.6 Lambdas

Daml supports inline functions, called `lambda`s. They are defined using the `(\x y z -> ...)` syntax. For example, a lambda version of `increment` would be `(\n -> n + 1)`.

11.12.3 Control Flow

In this section, we will cover branching and looping, and look at a few common patterns of how to translate procedural code into functional code.

11.12.3.1 Branching

Until [Composing Choices](#) the only real kind of control flow introduced has been `case`, which is a powerful tool for branching.

If ... Else

[Add Constraints to a Contract](#) also showed a seemingly self-explanatory `if ... else` expression, but didn't explain it further. Let's implement the function `boolToInt : Bool -> Int` which in typical fashion maps `True` to 1 and `False` to 0. Here is an implementation using `case`:

```
boolToInt b = case b of
  True -> 1
  False -> 0
```

If you write this function in the IDE, you'll get a warning from the linter:

```
Suggestion: Use if
Found:
case b of
  True -> 1
  False -> 0
Perhaps:
if b then 1 else 0
```

The linter knows the equivalence and suggests a better implementation:

```
boolToInt2 b = if b
  then 1
  else 0
```

In short: `if ... else` expressions are equivalent to `case` expressions, but can be easier to read.

Control Flow as Expressions

case and if ... else expressions really are control flow in the sense that they short-circuit:

```
doError t = case t of
  "True"  -> True
  "False" -> False
  _       -> error ("Not a Bool: " <> t)
```

This function behaves as you would expect: the error only gets evaluated if an invalid text is passed in.

This is different from functions, where all arguments are evaluated immediately:

```
ifelse b t e = if b then t else e
boom = ifelse True 1 (error "Boom")
```

In the above, boom is an error.

While providing proper control flow, case and if ... else expressions do result in a value when evaluated. You can actually see that in the function definitions above. Since each of the functions is defined just as a case or if ... else expression, the value of the evaluated function is just the value of the case or if ... else expression. Values have a type: the if ... else expression in boolToInt2 has type Int as that is what the function returns; similarly, the case expression in doError has type Bool. To be able to give such expressions an unambiguous type, each branch needs to have the same type. The below function does not compile as one branch tries to return an Int and the other a Text:

```
typeError b = if b
  then 1
  else "a"
```

If we need functions that can return two (or more) types of things we need to encode that in the return type. For two possibilities, it's common to use the Either type:

```
intOrText : Bool -> Either Int Text
intOrText b = if b
  then Left 1
  else Right "a"
```

When you have more than two possible types (and sometimes even just for two types), it can be clearer to define your own variant type to wrap all possibilities.

Branching in Actions

The most common case where this becomes important is inside do blocks. Say we want to create a contract of one type in one case, and of another type in another case. Let's say we have two template types and want to write a function that creates an S if a condition is met, and a T otherwise.

```
template T
  with
    p : Party
  where
```

(continues on next page)

(continued from previous page)

```

    signatory p

template S
  with
    p : Party
  where
    signatory p

```

It would be tempting to write a simple `if ... else`, but it won't typecheck if each branch returns a different type:

```

typeError b p = if b
  then create T with p
  else create S with p

```

We have two options:

1. Use the `Either` trick from above.
2. Get rid of the return types.

```

ifThenSElseT1 b p = if b
  then do
    cid <- create S with p
    return (Left cid)
  else do
    cid <- create T with p
    return (Right cid)

ifThenSElseT2 b p = if b
  then do
    create S with p
    return ()
  else do
    create T with p
    return ()

```

The latter is so common that there is a utility function in `DA.Action` to get rid of the return type: `void : Functor f => f a -> f ()`.

```

ifThenSElseT3 b p = if b
  then void (create S with p)
  else void (create T with p)

```

`void` also helps express control flow of the type `Create a T only if a condition is met`.

```

conditionalS b p = if b
  then void (create S with p)
  else return ()

```

Note that we still need the `else` clause of the same type `()`. This pattern is so common, it's encapsulated in the standard library function `DA.Action.when : (Applicative f) => Bool -> f () -> f ()`.

```

conditionalS2 b p = when b (void (create S with p))

```

Despite `when` looking like a simple function, the compiler does some magic so that it short-circuits evaluation just like `if ... else` and `case`. The following `noop` function is a no-op (i.e. does nothing), not an error as one might otherwise expect:

```
noop : Update () = when False (error "Foo")
```

With `case`, `if ... else`, `void` and `when`, you can express all branching. However, one additional feature you may want to learn is guards. They are not covered here, but can help avoid deeply nested `if ... else` blocks. Here's just one example. The Haskell sources at the beginning of the chapter cover this topic in more depth.

```
tellSize : Int -> Text
tellSize d
  | d < 0 = "Negative"
  | d == 0 = "Zero"
  | d == 1 = "Non-Zero"
  | d < 10 = "Small"
  | d < 100 = "Big"
  | d < 1000 = "Huge"
  | otherwise = "Enormous"
```

11.12.3.2 Looping

Other than branching, the most common form of control flow is looping. Looping is usually used to iteratively modify some state. We'll use JavaScript in this section to illustrate the procedural way of doing things.

```
function sum(intArr) {
  var result = 0;
  intArr.forEach (i => {
    result += i;
  });
  return result;
}
```

A more general loop looks like this:

```
function whileF(init, cont, step, finalize) {
  var state = init();
  while (cont(state)) {
    state = step(state);
  }
  return finalize(state);
}
```

In both cases, state is being mutated: `result` in the former, `state` in the latter. Values in Daml are immutable, so it needs to work differently. In Daml we will do this with folds and recursion.

Folds

Folds correspond to looping with an explicit iterator: `for` and `forEach` loops in procedural languages. The most common iterator is a list, as is the case in the `sum` function above. For such cases, Daml has the `foldl` function. The `l` stands for `left` and means the list is processed from the left. There is also a corresponding `foldr` which processes from the right.

```
foldl : (b -> a -> b) -> b -> [a] -> b
```

Let's give the type parameters semantic names. `b` is the state, `a` is an item. `foldl`'s first argument is a function which takes a state and an item and returns a new state. That's the equivalent of the inner block of the `forEach`. It then takes a state, which is the initial state, and a list of items, which is the iterator. The result is again a state. The `sum` function above can be translated to Daml almost instantly with those correspondences in mind:

```
sum ints = foldl (+) 0 ints
```

If we wanted to be more verbose, we could replace `(+)` with a lambda `\result i -> result + i` which makes the correspondence to `result += i` from the JavaScript clearer.

Almost all loops with explicit iterators can be translated to folds, though we have to take a bit of care with performance when it comes to translating `for` loops:

```
function sumArrs(arr1, arr2) {
  var l = min (arr1.length, arr2.length);
  var result = new int[l];
  for(var i = 0; i < l; i++) {
    result[i] = arr1[i] + arr2[i];
  }
  return result;
}
```

Translating the `for` into a `forEach` is easy if you can get your hands on an array containing values `[0..(l-1)]`. And that's how you do it in Daml, using `ranges`. `[0..(l-1)]` is shorthand for `enumFromTo 0 (l-1)`, which returns the list you'd expect.

Daml also has an operator `(!!)` : `[a] -> Int -> a` which returns an element in a list. You may now be tempted to write `sumArrs` like this:

```
sumArrs : [Int] -> [Int] -> [Int]
sumArrs arr1 arr2 =
  let l = min (length arr1) (length arr2)
      sumAtI i = (arr1 !! i) + (arr2 !! i)
  in foldl (\state i -> (sumAtI i) :: state) [] [1..(l-1)]
```

Unfortunately, that's not a very good approach. Lists in Daml are linked lists, which makes access using `(!!)` too slow for this kind of iteration. A better approach in Daml is to get rid of the `i` altogether and instead merge the lists first using the `zip` function, and then iterate over the zipped up lists:

```
sumArrs2 arr1 arr2 = foldl (\state (x, y) -> (x + y) :: state) [] (zip arr1 arr2)
```

`zip` : `[a] -> [b] -> [(a, b)]` takes two lists, and merges them into a single list where the first element is the 2-tuple containing the first element of the two input lists, and so on. It drops any left-over elements of the longer list, thus making the `min` logic unnecessary.

Maps

In effect, the lambda passed to `foldl` only wants to act on a single element of the (zipped-up) input list, but still has to manage the concatenation of the whole state. Acting on each element separately is a common-enough pattern that there is a specialized function for it: `map : (a -> b) -> [a] -> [b]`. Using it, we can rewrite `sumArr` to:

```
sumArrs3 arr1 arr2 = map (\(x, y) -> (x + y)) (zip arr1 arr2)
```

As a rule, use `map` if the result has the same shape as the input and you don't need to carry state from one iteration to the next. Use folds if you need to accumulate state in any way.

Recursion

If there is no explicit iterator, you can use recursion. Let's try to write a function that reverses a list, for example. We want to avoid `(!!)` so there is no sensible iterator here. Instead, we use recursion:

```
reverseWorker rev rem = case rem of
  [] -> rev
  x::xs -> reverseWorker (x::rev) xs
reverse xs = reverseWorker [] xs
```

You may be tempted to make `reverseWorker` a local definition inside `reverse`, but Daml only supports recursion for top-level functions so the recursive part `reverseWorker` has to be its own top-level function.

Folds and Maps in Action Contexts

The folds and `map` function above are pure in the sense introduced in [Add Constraints to a Contract](#): The functions used to map or process items have no side effects. If you have looked at the [Work with Dependencies](#) models, you'll have noticed `mapA`, `mapA_`, and `forA`, which seem to serve a similar role but within `Actions`. A good example is the `mapA` call in the `testMultiTrade` script:

```
let rels =
  [ Relationship chfbank alice
  , Relationship chfbank bob
  , Relationship gbpbank alice
  , Relationship gbpbank bob
  ]
[chfha, chfhb, gbpha, gbphb] <- mapA setupRelationship rels
```

Here we have a list of relationships (type `[Relationship]`) and a function `setupRelationship : Relationship -> Script (ContractId AssetHolder)`. We want the `AssetHolder` contracts for those relationships, i.e. something of type `[ContractId AssetHolder]`. Using the `map` function almost gets us there, but `map setupRelationship rels` would have type `[Update (ContractId AssetHolder)]`. This is a list of `Update` actions, each resulting in a `ContractId AssetHolder`. What we need is an `Update` action resulting in a `[ContractId AssetHolder]`. The list and `Update` are nested the wrong way around for our purposes.

Intuitively, it's clear how to fix this: we want the compound action consisting of performing each of the actions in the list in turn. There's a function for that: `sequence : Applicative m => [m a] -> m [a]`. It implements that intuition and allows us to take the `Update` out of the list, so to

speak. So we could write `sequence (map setupRelationship rels)`. This is so common that it's encapsulated in the `mapA` function, a possible implementation of which is

```
mapA f xs = sequence (map f xs)
```

The `A` in `mapA` stands for `Action`, and you'll find that many functions that have something to do with `looping` have an `A` equivalent. The most fundamental of all of these is `foldlA` : `Action m => (b -> a -> m b) -> b -> [a] -> m b`, a left fold with side effects. Here the inner function has a side-effect indicated by the `m` so the end result `m b` also has a side effect: the sum of all the side effects of the inner function.

To improve your familiarity with these concepts, try implementing `foldlA` in terms of `foldl`, as well as `sequence` and `mapA` in terms of `foldlA`. Here is one set of possible implementations:

```
foldlA2 fn init xs =
  let
    work accA x = do
      acc <- accA
      fn acc x
    in foldl work (pure init) xs

mapA2 fn xs =
  let
    work ys x = do
      y <- fn x
      return (y :: ys)
    in foldlA2 work [] xs

sequence2 actions =
  let
    work ys action = do
      y <- action
      return (y :: ys)
    in foldlA2 work [] actions
```

`forA` is just `mapA` with its arguments reversed. This is useful for readability if the list of items is already in a variable, but the function is a lengthy lambda.

```
[usdCid, chfCid] <- forA [usdCid, chfCid] (\cid -> submit alice do
  exerciseCmd cid SetObservers with
    newObservers = [bob]
)
```

Lastly, you'll have noticed that in some cases we used `mapA_`, not `mapA`. The underscore indicates that the result is not used, so `mapA_ fn xs fn == void (mapA fn xs)`. The Daml Linter will alert you if you could use `mapA_` instead of `mapA`, and similarly for `forA_`.

11.12.4 Next Up

You now know the basics of functions and control flow, both in pure and Action contexts. The [Work with Dependencies](#) example shows just how much can be done with just the tools you have encountered here, but there are many more tools at your disposal in the Daml Standard Library. It provides functions and typeclasses for many common circumstances and in [The Daml Standard Library](#), you'll get an overview of the library and learn how to search and browse it.

11.13 The Daml Standard Library

In [Data Types](#) and [Functional Programming 101](#) you learned how to define your own data types and functions. However, you don't have to implement everything from scratch. Daml comes with the [Daml Standard Library](#), which contains types, functions, and typeclasses that cover a large range of use cases.

In this chapter, you'll get an overview of the essentials and learn how to browse and search the library to find functions. Being proficient with the Standard Library will make you considerably more efficient writing Daml code. Specifically, this chapter covers:

- The Prelude
- Important types from the Standard Library, and associated functions and typeclasses
- Typeclasses
- Important typeclasses like `Functor`, `Foldable`, and `Traversable`
- How to search the Standard Library

To go in depth on some of these topics, the literature referenced in [The Haskell Connection](#) covers them in much greater detail. The Standard Library typeclasses like `Applicative`, `Foldable`, `Traversable`, `Action` (called `Monad` in Haskell), and many more, are the bread and butter of Haskell programmers.

Note: There is a project template `daml-intro-11` for this chapter, but it only contains a single source file with the code snippets embedded in this section.

11.13.1 The Prelude

You've already used a lot of functions, types, and typeclasses without importing anything. Functions like `create`, `exercise`, and `(==)`, types like `[]`, `(,)`, `Optional`, and typeclasses like `Eq`, `Show`, and `Ord`. These all come from the [Prelude](#). The Prelude is module that gets implicitly imported into every other Daml module and contains both Daml specific machinery as well as the essentials needed to work with the inbuilt types and typeclasses.

11.13.2 Important Types From the Prelude

In addition to the [Native Types](#), the Prelude defines a number of common types:

11.13.2.1 Lists

You've already met lists. Lists have two constructors `[]` and `x :: xs`, the latter of which is `prepend` in the sense that `1 :: [2] == [1, 2]`. In fact `[1, 2]` is just syntactical sugar for `1 :: 2 :: []`.

11.13.2.2 Tuples

In addition to the 2-tuple you have already seen, the Prelude contains definitions for tuples of size up to 15. Tuples allow you to store mixed data in an ad-hoc fashion. Common use-cases are return values from functions consisting of several pieces or passing around data in folds, as you saw in [Folds](#). An example of a relatively wide Tuple can be found in the test modules of the [Exception Handling](#) project. `Test.Intro.Asset.TradeSetup.tradeSetup` returns the allocated parties and active contracts in a long tuple. `Test.Intro.Asset.MultiTrade.testMultiTrade` puts them back into scope using pattern matching:

```
return (alice, bob, usdbank, eurbank, usdha, usdha, eurha, eurhb, usdCid,
↪eurCid)
```

```
(alice, bob, usdbank, eurbank, usdha, usdha, eurha, eurhb, usdCid, eurCid) <-↪
↪tradeSetup
```

Tuples, like lists have some syntactic magic. Both the types as well as the constructors for tuples are `(,,,)` where the number of commas determines the arity of the tuple. Type and data constructor can be applied with values inside the brackets, or outside, and partial application is possible:

```
t1 : (Int, Text) = (1, "a")
t2 : (,) Int Text = (1, "a")
t3 : (Int, Text) = (1,) "a"
t4 : a -> (a, Text) = (,"a")
```

Note: While tuples of great lengths are available, it is often advisable to define custom records with named fields for complex structures or long-lived values. Overuse of tuples can harm code readability.

11.13.2.3 Optional

The `Optional` type represents a value that may be missing. It's the closest thing Daml has to a `null`-able value. `Optional` has two constructors: `Some`, which takes a value, and `None`, which doesn't take a value. In many languages one would write code like this:

```
lookupResult = lookupByKey(k);

if( lookupResult == null) {
```

(continues on next page)

(continued from previous page)

```
// Do something
} else {
  // Do something else
}
```

In Daml the same thing would be expressed as:

```
lookupResult <- lookupByKey @T k
case lookupResult of
  None -> do -- Do Something
    return ()
  Some cid -> do -- Do Something
    return ()
```

11.13.2.4 Either

`Either` is used in cases where a value should store one of two types. It has two constructors, `Left` and `Right`, each of which take a value of one or the other of the two types. One typical use-case of `Either` is as an extended `Optional` where `Right` takes the role of `Some` and `Left` the role of `None`, but with the ability to store an error value. `Either Text`, for example behaves just like `Optional`, except that values with constructor `Left` have a text associated to them.

Note: As with tuples, it's easy to overuse `Either` and harm readability. Consider writing your own more explicit type instead. For example if you were returning `South a` vs `North b` using your own type over `Either` would make your code clearer.

11.13.3 Typeclasses

You've seen typeclasses in use all the way from [Data Types](#). It's now time to look under the hood.

Typeclasses are declared using the `class` keyword:

```
class HasQuantity a q where
  getQuantity : a -> q
  setQuantity : q -> a -> a
```

This is akin to an interface declaration of an interface with a getter and setter for a quantity. To implement this interface, you need to define instances of this typeclass:

```
data Foo = Foo with
  amount : Decimal

instance HasQuantity Foo Decimal where
  getQuantity foo = foo.amount
  setQuantity amount foo = foo with amount
```

Typeclasses can have constraints like functions. For example: `class Eq a => Ord a` means everything that is orderable can also be compared for equality. And that's almost all there's to it.

11.13.4 Important Typeclasses From the Prelude

11.13.4.1 Eq

The `Eq` typeclass allows values of a type to be compared for (in)-equality. It makes available two function: `==` and `/=`. Most data types from the Standard Library have an instance of `Eq`. As you already learned in [Data Types](#), you can let the compiler automatically derive instances of `Eq` for you using the `deriving` keyword.

Templates always have an `Eq` instance, and all types stored on a template need to have one.

11.13.4.2 Ord

The `Ord` typeclass allows values of a type to be compared for order. It makes available functions: `<`, `>`, `<=`, and `>=`. Most of the inbuilt data types have an instance of `Ord`. Furthermore, types like `List` and `Optional` get an instance of `Ord` if the type they contain has one. You can let the compiler automatically derive instances of `Ord` for you using the `deriving` keyword.

11.13.4.3 Show

`Show` indicates that a type can be serialized to `Text`, ie `shown` in a shell. Its key function is `show`, which takes a value and converts it to `Text`. All inbuilt data types have an instance for `Show` and types like `List` and `Optional` get an instance if the type they contain has one. It also supports the `deriving` keyword.

11.13.4.4 Functor

[Functors](#) are the closest thing to `containers` that Daml has. Whenever you see a type with a single type parameter, you are probably looking at a Functor: `[a]`, `Optional a`, `Either Text a`, `Update a`. Functors are things that can be mapped over and as such, the key function of `Functor` is `fmap`, which does generically what the `map` function does for lists.

Other classic examples of Functors are `Sets`, `Maps`, `Trees`, etc.

11.13.4.5 Applicative Functor

[Applicative Functors](#) are a bit like `Actions`, which you met in [Add Constraints to a Contract](#), except that you can't use the result of one action as the input to another action. The only important Applicative Functor that isn't an action in Daml is the `Commands` type submitted in a `submit` block in Daml Script. That's why in order to use `do` notation in Daml Script, you have to enable the `ApplicativeDo` language extension.

11.13.4.6 Actions

[Actions](#) were already covered in [Add Constraints to a Contract](#). One way to think of them is as recipes for a value, which need to be executed to get at that value. Actions are always Functors (and Applicative Functors). The intuition for that is simply that `fmap f x` is the recipe in `x` with the extra instruction to apply the pure function `f` to the result.

The really important Actions in Daml are `Update` and `Script`, but there are many others, like `[]`, `Optional`, and `Either a`.

11.13.4.7 Semigroups and Monoids

[Semigroups and monoids](#) are about binary operations, but in practice, their important use is for `Text` and `[]`, where they allow concatenation using the `{<>}` operator.

11.13.4.8 Additive and Multiplicative

[Additive and Multiplicative](#) abstract out arithmetic operations, so that `(+)`, `(-)`, `(*)`, and some other functions can be used uniformly between `Decimal` and `Int`.

11.13.5 Important Modules in the Standard Library

For almost all the types and typeclasses presented above, the Standard Library contains a module:

- [DA.List](#) for Lists
- [DA.Optional](#) for `Optional`
- [DA.Tuple](#) for Tuples
- [DA.Either](#) for `Either`
- [DA.Functor](#) for Functors
- [DA.Action](#) for Actions
- [DA.Monoid](#) and [DA.Semigroup](#) for Monoids and Semigroups
- [DA.Text](#) for working with `Text`
- [DA.Time](#) for working with `Time`
- [DA.Date](#) for working with `Date`

You get the idea, the names are fairly descriptive.

Other than the typeclasses defined in Prelude, there are two modules generalizing concepts you've already learned, which are worth knowing about: `Foldable` and `Traversable`. In [Looping](#) you learned all about folds and their Action equivalents. All the examples there were based on lists, but there are many other possible iterators. This is expressed in two additional typeclasses: [DA.Traversable](#), and [DA.Foldable](#). For more detail on these concepts, please refer to the literature in [The Haskell Connection](#), or https://wiki.haskell.org/Foldable_and_Traversable.

11.13.6 Search the Standard Library

Being able to browse the Standard Library starting from [The Standard Library](#) is a start, and the module naming helps, but it's not an efficient process for finding out what a function you've encountered does, even less so for finding a function that does a thing you need to do.

Daml has its own version of the [Hoogle](#) search engine, which offers search both by name and by signature. This function is fully integrated into the search bar on <https://docs.daml.com/>, but for those wanting a pure Standard Library search, it's also available on <https://hoogle.daml.com>.

11.13.6.1 Search for Functions by Name

Say you come across some functions you haven't seen before, like the ones in the `ensure` clause of the `MultiTrade`.

```
ensure (length baseAssetCids == length baseAssets) &&
  (length quoteApprovalCids == length quoteAssets) &&
  not (null baseAssets) &&
  not (null quoteAssets)
```

You may be able to guess what `not` and `null` do, but try searching those names in the documentation search. Search results from the Standard Library will show on top. `not`, for example, gives

```
not
: Bool -> Bool
Boolean "not"
```

Signature (including type constraints) and description usually give a pretty clear picture of what a function does.

11.13.6.2 Search for Functions by Signature

The other very common use case for the search is that you have some values that you want to do something with, but don't know the standard library function you need. On the `MultiTrade` template we have a list `baseAssets`, and thanks to your `ensure` clause we know it's non-empty. In the original `Trade` we used `baseAsset.owner` as the signatory. How do you get the first element of this list to extract the `owner` without going through the motions of a complete pattern match using `case`?

The trick is to think about the signature of the function that's needed, and then to search for that signature. In this case, we want a single distinguished element from a list so the signature should be `[a] -> a`. If you search for that, you'll get a whole range of results, but again, Standard Library results are shown at the top.

Scanning the descriptions, `head` is the obvious choice, as used in the `let` of the `MultiTrade` template.

You may notice that in the search results you also get some hits that don't mention `[]` explicitly. For example:

The reason is that there is an instance for `Foldable [a]`.

Let's try another search. Suppose you didn't want the first element, but the one at index n . Remember that $(!!)$ operator from [Functional Programming 101](#)? There are now two possible signatures we could search for: `[a] -> Int -> a` and `Int -> [a] -> a`. Try searching for both. You'll see that the search returns $(!!)$ in both cases. You don't have to worry about the order of arguments.

11.13.7 Next Up

In the following section, you'll find options for testing and interacting with Daml code. We also talk about the operational semantics of some keywords and their commonly associated failures, and a little bit about how coverage reports work in Daml testing.

11.14 Good Design Patterns

Patterns have been useful in the programming world, as both a source of design inspiration, and a document of good design practices. This document is a catalog of Daml patterns intended to provide the same facility in the Daml application world.

You can checkout the examples locally via `daml new daml-patterns --template daml-patterns`.

The Propose and Accept Pattern The Propose and Accept pattern demonstrates how to start a bilateral workflow. One party creates a proposal or an invite contract. This gives another party the chance to accept, reject, or renegotiate.

The Multiple Party Agreement Pattern The Multiple Party Agreement pattern uses a Pending contract as a wrapper for the Agreement contract. Any one of the signatory parties can kick off the workflow by creating a Pending contract on the ledger, filling in themselves in all the signatory fields. The Agreement contract is not created on the ledger until all parties have agreed to the Pending contract, and replaced the initiator's signature with their own.

The Delegation Pattern The Delegation pattern gives one party the right to exercise a choice on behalf of another party. The agent can control a contract on the ledger without the principal explicitly committing the action.

The Authorization Pattern The Authorization pattern demonstrates how to make sure a controlling party is authorized before they take certain actions.

The Locking Pattern The Locking pattern exhibits how to achieve locking safely and efficiently in Daml. Only the specified locking party can lock the asset through an active and authorized action. When a contract is locked, some or all choices specified on that contract may not be exercised.

11.14.1 The Propose and Accept Pattern

The Propose and Accept pattern demonstrates how to start a bilateral workflow. One party creates a proposal or an invite contract. This gives another party the chance to accept, reject, or renegotiate.

11.14.1.1 Motivation

It takes two to tango, but one party has to propose. It is no different in the business world. The contractual relationship between two businesses often starts with an invite, a business proposal, a bid offering, etc.

Invite When a market operator wants to set up a market, they need to go through an onboarding process in which they invite participants to sign master service agreements and fulfill different roles in the market. Receiving participants need to evaluate the rights and responsibilities of each role and respond accordingly.

Propose When issuing an asset, an issuer is making a business proposal to potential buyers. The proposal lays out what is expected from buyers, and what they can expect from the issuer. Buyers need to evaluate all aspects of the offering, e.g. price, return, and tax implications, before making a decision.

The Propose and Accept pattern demonstrates how to write a Daml program to model the initiation of an inter-company contractual relationship. Daml modelers often have to follow this pattern to ensure that no participant is forced into an obligation.

11.14.1.2 Implementation

The Propose and Accept pattern in general involves two contracts, the proposal contract and the result contract:

Proposal Contract The proposal contract can be created from a role contract or any other point in the workflow. In this example, the proposal contract is the proposal contract *CoinIssueProposal* which the issuer created from the master contract *CoinMaster*.

```
template CoinMaster
  with
    issuer: Party
  where
    signatory issuer

    nonconsuming choice Invite : ContractId CoinIssueProposal
      with owner: Party
      controller issuer
      do create CoinIssueProposal
        with coinAgreement = CoinIssueAgreement with issuer; owner
```

The *CoinIssueProposal* contract has *Issuer* as the signatory and *Owner* as the controller to the Accept choice. In its complete form, the *CoinIssueProposal* contract should define all choices available to the owner, i.e. Accept, Reject or Counter (re-negotiate terms).

```
template CoinIssueProposal
  with
    coinAgreement: CoinIssueAgreement
  where
    signatory coinAgreement.issuer
    observer coinAgreement.owner

    choice AcceptCoinProposal
      : ContractId CoinIssueAgreement
      controller coinAgreement.owner
      do create coinAgreement
```

Result Contract Once the owner exercises the *AcceptCoinProposal* choice on the proposal contract to express their consent, it returns a result contract representing the agreement between the two parties. In this example, the result contract is of type *CoinIssueAgreement*. Note, it has both issuer and owner as the signatories, implying they both need to consent to the creation of this contract. Both parties could be controller(s) on the result contract, depending on the business case.

```
template CoinIssueAgreement
  with
    issuer: Party
    owner: Party
  where
    signatory issuer, owner

    nonconsuming choice Issue : ContractId Coin
      with amount: Decimal
      controller issuer
      do create Coin with issuer; owner; amount; delegates = []
```

Fig. 1: Propose and Accept pattern diagram

11.14.1.3 Trade-offs

Propose and Accept can be quite verbose if signatures from more than two parties are required to progress the workflow.

11.14.2 The Multiple Party Agreement Pattern

The Multiple Party Agreement pattern uses a Pending contract as a wrapper for the Agreement contract. Any one of the signatory parties can kick off the workflow by creating a Pending contract on the ledger, filling in themselves in all the signatory fields. The Agreement contract is not created on the ledger until all parties have agreed to the Pending contract, and replaced the initiator's signature with their own.

11.14.2.1 Motivation

The *The Propose and Accept Pattern* shows how to create bilateral agreements in Daml. However, a project or a workflow often requires more than two parties to reach a consensus and put their signatures on a multi-party contract. For example, in a large construction project, there are at least three major stakeholders: Owner, Architect and Builder. All three parties need to establish agreement on key responsibilities and project success criteria before starting the construction.

If such an agreement were modeled as three separate bilateral agreements, no party could be sure if there are conflicts between their two contracts and the third contract between their partners. If the *The Propose and Accept Pattern* were used to collect three signatures on a multi-party agreement, unnecessary restrictions would be put on the order of consensus and a number of additional contract templates would be needed as the intermediate steps. Both solution are suboptimal.

Following the Multiple Party Agreement pattern, it is easy to write an agreement contract with multiple signatories and have each party accept explicitly.

11.14.2.2 Implementation

Agreement contract The *Agreement* contract represents the final agreement among a group of stakeholders. Its content can vary per business case, but in this pattern, it always has multiple signatories.

```
template Agreement
  with
    signatories: [Party]
  where
    signatory signatories
  ensure
    unique signatories
  -- The rest of the template to be agreed to would follow here
```

Pending contract The *Pending* contract needs to contain the contents of the proposed *Agreement* contract, as a parameter. This is so that parties know what they are agreeing to, and also so that when all parties have signed, the *Agreement* contract can be created.

The *Pending* contract has a list of parties who have signed it, and a list of parties who have yet to sign it. If you add these lists together, it has to be the same set of parties as the *signatories* of the *Agreement* contract.

All of the *toSign* parties have the choice to *Sign*. This choice checks that the party is indeed a member of *toSign*, then creates a new instance of the *Pending* contract where they have been moved to the *signed* list.

```
-- | The parties who need to sign are the finalContract.signatories with
  ↪alreadySigned filtered out
toSign : Pending -> [Party]
toSign Pending { alreadySigned, finalContract } =
  filter (`notElem` alreadySigned) finalContract.signatories

template Pending
  with
    finalContract: Agreement
    alreadySigned: [Party]
  where
    signatory alreadySigned
```

(continues on next page)

(continued from previous page)

```

observer finalContract.signatories
ensure
  -- Can't have duplicate signatories
  unique alreadySigned

choice Sign : ContractId Pending with
  signer : Party
  controller signer
  do
    -- Check the controller is in the toSign list, and if they are,
    ↪sign the Pending contract
    assert (signer `elem` toSign this)
    create this with alreadySigned = signer :: alreadySigned

```

Once all of the parties have signed, any of them can create the final Agreement contract using the `Finalize` choice. This checks that all of the signatories for the Agreement have signed the Pending contract.

```

choice Finalize : ContractId Agreement with
  signer : Party
  controller signer
  do
    -- Check that all the required signatories have signed Pending
    assert (sort alreadySigned == sort finalContract.signatories)
    create finalContract

```

Collecting the signatures in practice Since the final Pending contract has multiple signatories, it cannot be created in that state by any one stakeholder.

However, a party can create a pending contract, with all of the other parties in the `toSign` list.

```

parties@[person1, person2, person3, person4] <- makePartiesFrom ["Alice",
↪"Bob", "Clare", "Dave"]
let finalContract = Agreement with signatories = parties

-- Parties cannot create a contract already signed by someone else
initialFailTest <- person1 `submitMustFail` do
  createCmd Pending with finalContract; alreadySigned = [person1, person2]

-- Any party can create a Pending contract provided they list themselves as
↪the only signatory
pending <- person1 `submit` do
  createCmd Pending with finalContract; alreadySigned = [person1]

```

Once the Pending contract is created, the other parties can sign it. For simplicity, the example code only has choices to express consensus (but you might want to add choices to Accept, Reject, or Negotiate).

```

-- Each signatory of the finalContract can Sign the Pending contract
pending <- person2 `submit` do
  exerciseCmd pending Sign with signer = person2
pending <- person3 `submit` do
  exerciseCmd pending Sign with signer = person3
pending <- person4 `submit` do
  exerciseCmd pending Sign with signer = person4

-- A party can't sign the Pending contract twice

```

(continues on next page)

(continued from previous page)

```

pendingFailTest <- person3 `submitMustFail` do
  exerciseCmd pending Sign with signer = person3
  -- A party can't sign on behalf of someone else
pendingFailTest <- person3 `submitMustFail` do
  exerciseCmd pending Sign with signer = person4

```

Once all of the parties have signed the Pending contract, any of them can then exercise the **Finalize** choice. This creates the Agreement contract on the ledger.

```

person1 `submit` do
  exerciseCmd pending Finalize with signer = person1

```

Fig. 2: Multiple Party Agreement Diagram

11.14.3 The Delegation Pattern

The Delegation pattern gives one party the right to exercise a choice on behalf of another party. The agent can control a contract on the ledger without the principal explicitly committing the action.

11.14.3.1 Motivation

Delegation is prevalent in the business world. In fact, the entire custodian business is based on delegation. When a company chooses a custodian bank, it is effectively giving the bank the rights to hold their securities and settle transactions on their behalf. The securities are not legally possessed by the custodian banks, but the banks should have full rights to perform actions in the client's name, such as making payments or changing investments.

The Delegation pattern enables Daml modelers to model the real-world business contractual agreements between custodian banks and their customers. Ownership and administration rights can be segregated easily and clearly.

11.14.3.2 Implementation

Pre-condition: There exists a contract, on which controller Party A has a choice and intends to delegate execution of the choice to Party B. In this example, the owner of a *Coin* contract intends to delegate the *Transfer* choice.

```
template Coin
  with
    owner: Party
    issuer: Party
    amount: Decimal
    delegates : [Party]
  where
    signatory issuer, owner
    observer delegates
```

```
choice Transfer : ContractId TransferProposal
  with newOwner: Party
  controller owner
  do
    create TransferProposal
      with coin=this; newOwner
```

Delegation Contract

Principal, the original coin owner, is the signatory of delegation contract *CoinPoA*. This signatory is required to authorize the *Transfer* choice on *coin*.

```
template CoinPoA
  with
    attorney: Party
    principal: Party
  where
    signatory principal
    observer attorney

    choice WithdrawPoA
      : ()
      controller principal
      do return ()
```

Whether or not the *Attorney* party should be a signatory of *CoinPoA* is subject to the business agreements between *Principal* and *Attorney*. For simplicity, in this example, *Attorney* is not a signatory.

Attorney is the controller of the Delegation choice on the contract. Within the choice, *Principal* exercises the choice *Transfer* on the *Coin* contract.

```
nonconsuming choice TransferCoin
  : ContractId TransferProposal
  with
    coinId: ContractId Coin
    newOwner: Party
  controller attorney
  do
    exercise coinId Transfer with newOwner
```

Coin contracts need to be disclosed to *Attorney* before they can be used in an exercise of *Transfer*. This can be done by adding *Attorney* to *Coin* as an Observer. This can be done

dynamically, for any specific *Coin*, by making the observers a *List*, and adding a choice to add a party to that List:

```
choice Disclose : ContractId Coin
  with p : Party
  controller owner
  do create this with delegates = p :: delegates
```

Note: The technique is likely to change in the future. Daml is actively researching future language features for contract disclosure.

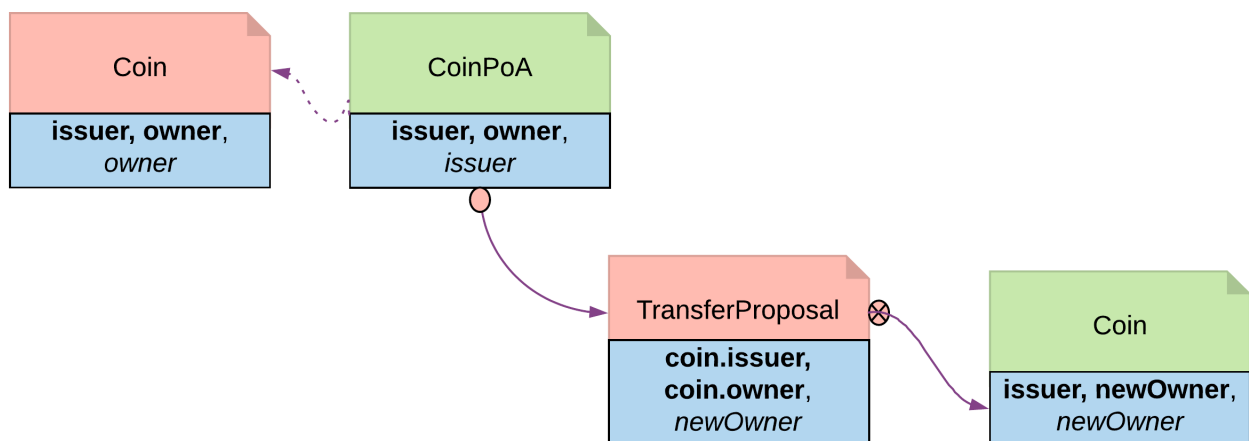

Fig. 3: Delegation pattern diagram

11.14.4 The Authorization Pattern

The Authorization pattern demonstrates how to make sure a controlling party is authorized before they take certain actions.

11.14.4.1 Motivation

Authorization is an universal concept in the business world as access to most business resources is a privilege, and not given freely. For example, security trading may seem to be a plain bilateral agreement between the two trading counterparties, but this could not be further from truth. To be able to trade, the trading parties need go through a series of authorization processes and gain permission from a list of service providers such as exchanges, market data streaming services, clearing houses and security registrars etc.

The Authorization pattern shows how to model these authorization checks prior to a business transaction.

11.14.4.2 Authorization

Here is an implementation of a *Coin* transfer without any authorization:

```
template Coin
  with
    owner: Party
    issuer: Party
    amount: Decimal
    delegates : [Party]
  where
    signatory issuer, owner
    observer delegates
```

```
choice Transfer : ContractId TransferProposal
  with newOwner: Party
  controller owner
  do
    create TransferProposal
      with coin=this; newOwner
```

This is may be insufficient since the issuer has no means to ensure the newOwner is an accredited company. The following changes fix this deficiency.

Authorization contract The below shows an authorization contract *CoinOwnerAuthorization*. In this example, the issuer is the only signatory so it can be easily created on the ledger. Owner is an observer on the contract to ensure they can see and use the authorization.

```
template CoinOwnerAuthorization
  with
    owner: Party
    issuer: Party
  where
    signatory issuer
    observer owner

    choice WithdrawAuthorization
      : ()
      controller issuer
      do return ()
```

Authorization contracts can have much more advanced business logic, but in its simplest form, *CoinOwnerAuthorization* serves its main purpose, which is to prove the owner is a warranted coin owner.

TransferProposal contract In the *TransferProposal* contract, the *Accept* choice checks that newOwner has proper authorization. A *CoinOwnerAuthorization* for the new owner has to be supplied and is checked by the two *assert* statements in the choice before a coin can be transferred.

```
choice AcceptTransfer
  : ContractId Coin
  with token: ContractId CoinOwnerAuthorization
  controller newOwner
  do
    t <- fetch token
    assert (coin.issuer == t.issuer)
    assert (newOwner == t.owner)
    create coin with owner = newOwner
```

Fig. 4: Authorization Diagram

11.14.5 The Locking Pattern

The Locking pattern exhibits how to achieve locking safely and efficiently in Daml. Only the specified locking party can lock the asset through an active and authorized action. When a contract is locked, some or all choices specified on that contract may not be exercised.

11.14.5.1 Motivation

Locking is a common real-life requirement in business transactions. During the clearing and settlement process, once a trade is registered and novated to a central Clearing House, the trade is considered locked-in. This means the securities under the ownership of seller need to be locked so they cannot be used for other purposes, and so should be the funds on the buyer's account. The locked state should remain throughout the settlement Payment versus Delivery process. Once the ownership is exchanged, the lock is lifted for the new owner to have full access.

11.14.5.2 Implementation

There are three ways to achieve locking:

11.14.5.3 Lock by Archiving

Pre-condition: there exists a contract that needs to be locked and unlocked. In this section, *Coin* is used as the original contract to demonstrate locking and unlocking.

```
template Coin
  with
    owner: Party
    issuer: Party
    amount: Decimal
```

(continues on next page)

(continued from previous page)

```

delegates : [Party]
where
  signatory issuer, owner
  observer delegates

```

```

choice Transfer : ContractId TransferProposal
  with newOwner: Party
  controller owner
  do
    create TransferProposal
      with coin=this; newOwner

```

```

--a coin can only be archived by the issuer under the condition that the
↪ issuer is the owner of the coin. This ensures the issuer cannot archive coins
↪ at will.
choice Archives
  : ()
  controller issuer
  do assert (issuer == owner)

```

Archiving is a straightforward choice for locking because once a contract is archived, all choices on the contract become unavailable. Archiving can be done either through consuming choice or archiving contract.

Consuming Choice

The steps below show how to use a consuming choice in the original contract to achieve locking:

Add a consuming choice, *Lock*, to the *Coin* template that creates a *LockedCoin*.

The controller party on the *Lock* may vary depending on business context. In this example, *owner* is a good choice.

The parameters to this choice are also subject to business use case. Normally, it should at least have locking terms (e.g. lock expiry time) and a party authorized to unlock.

```

choice Lock : ContractId LockedCoin
  with maturity: Time; locker: Party
  controller owner
  do create LockedCoin with coin=this; maturity; locker

```

Create a *LockedCoin* to represent *Coin* in the locked state. *LockedCoin* has the following characteristics, all in order to be able to recreate the original *Coin*:

- The signatories are the same as the original contract.
- It has all data of *Coin*, either through having a *Coin* as a field, or by replicating all data of *Coin*.
- It has an *Unlock* choice to lift the lock.

```

template LockedCoin
  with
    coin: Coin
    maturity: Time
    locker: Party
  where

```

(continues on next page)

(continued from previous page)

```

signatory coin.issuer, coin.owner
observer locker

```

```

choice Unlock
  : ContractId Coin
  controller locker
  do create coin

```

Fig. 5: Locking By Consuming Choice Diagram

Archiving Contract

In the event that changing the original contract is not desirable and assuming the original contract already has an Archive choice, you can introduce another contract, *CoinCommitment*, to archive *Coin* and create *LockedCoin*.

Examine the controller party and archiving logic in the *Archives* choice on the *Coin* contract. A coin can only be archived by the issuer under the condition that the issuer is the owner of the coin. This ensures the issuer cannot archive any coin at will.

```

--a coin can only be archived by the issuer under the condition that the
--issuer is the owner of the coin. This ensures the issuer cannot archive coins
--at will.
choice Archives
  : ()
  controller issuer
  do assert (issuer == owner)

```

Since we need to call the *Archives* choice from *CoinCommitment*, its signatory has to be *Issuer*.

```

template CoinCommitment
  with
    owner: Party
    issuer: Party
    amount: Decimal
  where
    signatory issuer
    observer owner

```

The controller party and parameters on the *Lock* choice are the same as described in locking by consuming choice. The additional logic required is to transfer the asset to the issuer, and then explicitly call the *Archive* choice on the *Coin* contract.

Once a *Coin* is archived, the *Lock* choice creates a *LockedCoin* that represents *Coin* in locked state.

```

nonconsuming choice LockCoin
: ContractId LockedCoin
with coinCid: ContractId Coin
  maturity: Time
  locker: Party
controller owner
do
  inputCoin <- fetch coinCid
  assert (inputCoin.owner == owner && inputCoin.issuer == issuer &&
    ↪inputCoin.amount == amount )
  --the original coin firstly transferred to issuer and then archived
  prop <- exercise coinCid Transfer with newOwner = issuer
  do
    id <- exercise prop AcceptTransfer
    exercise id Archives
  --create a lockedCoin to represent the coin in locked state
  create LockedCoin with
    coin=inputCoin with owner; issuer; amount
    maturity; locker

```

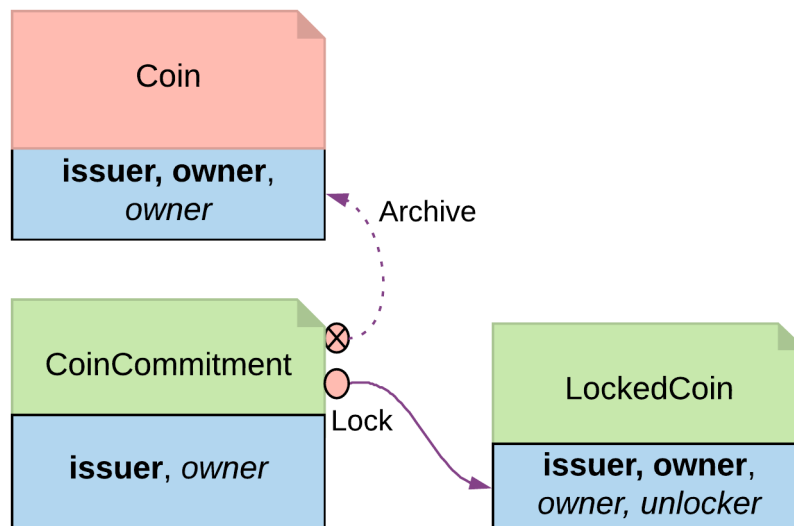

Fig. 6: Locking By Archiving Contract Diagram

Trade-offs

This pattern achieves locking in a fairly straightforward way. However, there are some tradeoffs.

Locking by archiving disables all choices on the original contract. Usually for consuming choices this is exactly what is required. But if a party needs to selectively lock only some choices, remaining active choices need to be replicated on the *LockedCoin* contract, which can lead to code duplication.

The choices on the original contract need to be altered for the lock choice to be added. If this contract is shared across multiple participants, it will require agreement from all involved.

11.14.5.4 Lock by State

The original Coin template is shown below. This is the basis on which to implement locking by state

```
template Coin
with
  owner: Party
  issuer: Party
  amount: Decimal
  delegates : [Party]
where
  signatory issuer, owner
  observer delegates
```

```
choice Transfer : ContractId TransferProposal
with newOwner: Party
controller owner
do
  create TransferProposal
  with coin=this; newOwner
```

```
--a coin can only be archived by the issuer under the condition that the
↪ issuer is the owner of the coin. This ensures the issuer cannot archive coins
↪ at will.
```

```
choice Archives
: ()
controller issuer
do assert (issuer == owner)
```

In its original form, all choices are actionable as long as the contract is active. Locking by State requires introducing fields to track state. This allows for the creation of an active contract in two possible states: locked or unlocked. A Daml modeler can selectively make certain choices actionable only if the contract is in unlocked state. This effectively makes the asset lockable.

The state can be stored in many ways. This example demonstrates how to create a *LockableCoin* through a party. Alternatively, you can add a lock contract to the asset contract, use a boolean flag or include lock activation and expiry terms as part of the template parameters.

Here are the changes we made to the original Coin contract to make it lockable.

Add a *locker* party to the template parameters.

Define the states.

- if owner == locker, the coin is unlocked
- if owner != locker, the coin is in a locked state

The contract state is checked on choices.

- *Transfer* choice is only actionable if the coin is unlocked
- *Lock* choice is only actionable if the coin is unlocked and a 3rd party locker is supplied
- *Unlock* is available to the locker party only if the coin is locked

```
template LockableCoin
with
  owner: Party
  issuer: Party
  amount: Decimal
  locker: Party
```

(continues on next page)

(continued from previous page)

```

where
  signatory issuer
  signatory owner
  observer locker

ensure amount > 0.0

--Transfer can happen only if it is not locked
choice Transfer : ContractId TransferProposal
  with newOwner: Party
  controller owner
  do
    assert (locker == owner)
    create TransferProposal
      with coin=this; newOwner

    --Lock can be done if owner decides to bring a locker on board
  choice Lock : ContractId LockableCoin
    with newLocker: Party
    controller owner
    do
      assert (newLocker /= owner)
      create this with locker = newLocker

    --Unlock only makes sense if the coin is in locked state
  choice Unlock
    : ContractId LockableCoin
    controller locker
    do
      assert (locker /= owner)
      create this with locker = owner

```

Locking By State Diagram

Trade-offs

It requires changes made to the original contract template. Furthermore you should need to change all choices intended to be locked.

If locking and unlocking terms (e.g. lock triggering event, expiry time, etc) need to be added to the template parameters to track the state change, the template can get overloaded.

11.14.5.5 Lock by Safekeeping

Safekeeping is a realistic way to model locking as it is a common practice in many industries. For example, during a real estate transaction, purchase funds are transferred to the sellers lawyer's escrow account after the contract is signed and before closing. To understand its implementation, review the original *Coin* template first.

```
template Coin
with
  owner: Party
  issuer: Party
  amount: Decimal
  delegates : [Party]
where
  signatory issuer, owner
  observer delegates
```

```
choice Transfer : ContractId TransferProposal
with newOwner: Party
  controller owner
do
  create TransferProposal
  with coin=this; newOwner
```

```
--a coin can only be archived by the issuer under the condition that the
↪ issuer is the owner of the coin. This ensures the issuer cannot archive coins
↪ at will.
choice Archives
: ()
  controller issuer
do assert (issuer == owner)
```

There is no need to make a change to the original contract. With two additional contracts, we can transfer the *Coin* ownership to a locker party.

Introduce a separate contract template *LockRequest* with the following features:

- *LockRequest* has a locker party as the single signatory, allowing the locker party to unilaterally initiate the process and specify locking terms.
- Once owner exercises *Accept* on the lock request, the ownership of coin is transferred to the locker.
- The *Accept* choice also creates a *LockedCoinV2* that represents *Coin* in locked state.

```
template LockRequest
with
  locker: Party
  maturity: Time
```

(continues on next page)

(continued from previous page)

```

coin: Coin
where
  signatory locker
  observer coin.owner

choice Accept : LockResult
  with coinCid : ContractId Coin
  controller coin.owner
  do
    inputCoin <- fetch coinCid
    assert (inputCoin == coin)
    tpCid <- exercise coinCid Transfer with newOwner = locker
    coinCid <- exercise tpCid AcceptTransfer
    lockCid <- create LockedCoinV2 with locker; maturity; coin
    return LockResult {coinCid; lockCid}

```

LockedCoinV2 represents *Coin* in the locked state. It is fairly similar to the *LockedCoin* described in [Consuming Choice](#). The additional logic is to transfer ownership from the locker back to the owner when *Unlock* or *Clawback* is called.

```

template LockedCoinV2
  with
    coin: Coin
    maturity: Time
    locker: Party
  where
    signatory locker, coin.owner

  choice UnlockV2
    : ContractId Coin
    with coinCid : ContractId Coin
    controller locker
    do
      inputCoin <- fetch coinCid
      assert (inputCoin.owner == locker)
      tpCid <- exercise coinCid Transfer with newOwner = coin.owner
      exercise tpCid AcceptTransfer

  choice ClawbackV2
    : ContractId Coin
    with coinCid : ContractId Coin
    controller coin.owner
    do
      currTime <- getTime
      assert (currTime >= maturity)
      inputCoin <- fetch coinCid
      assert (inputCoin == coin with owner=locker)
      tpCid <- exercise coinCid Transfer with newOwner = coin.owner
      exercise tpCid AcceptTransfer

```

Fig. 7: Locking By Safekeeping Diagram

Trade-offs

Ownership transfer may give the locking party too much access on the locked asset. A rogue lawyer could run away with the funds. In a similar fashion, a malicious locker party could introduce code to transfer assets away while they are under their ownership.

11.14.6 Diagram Legends

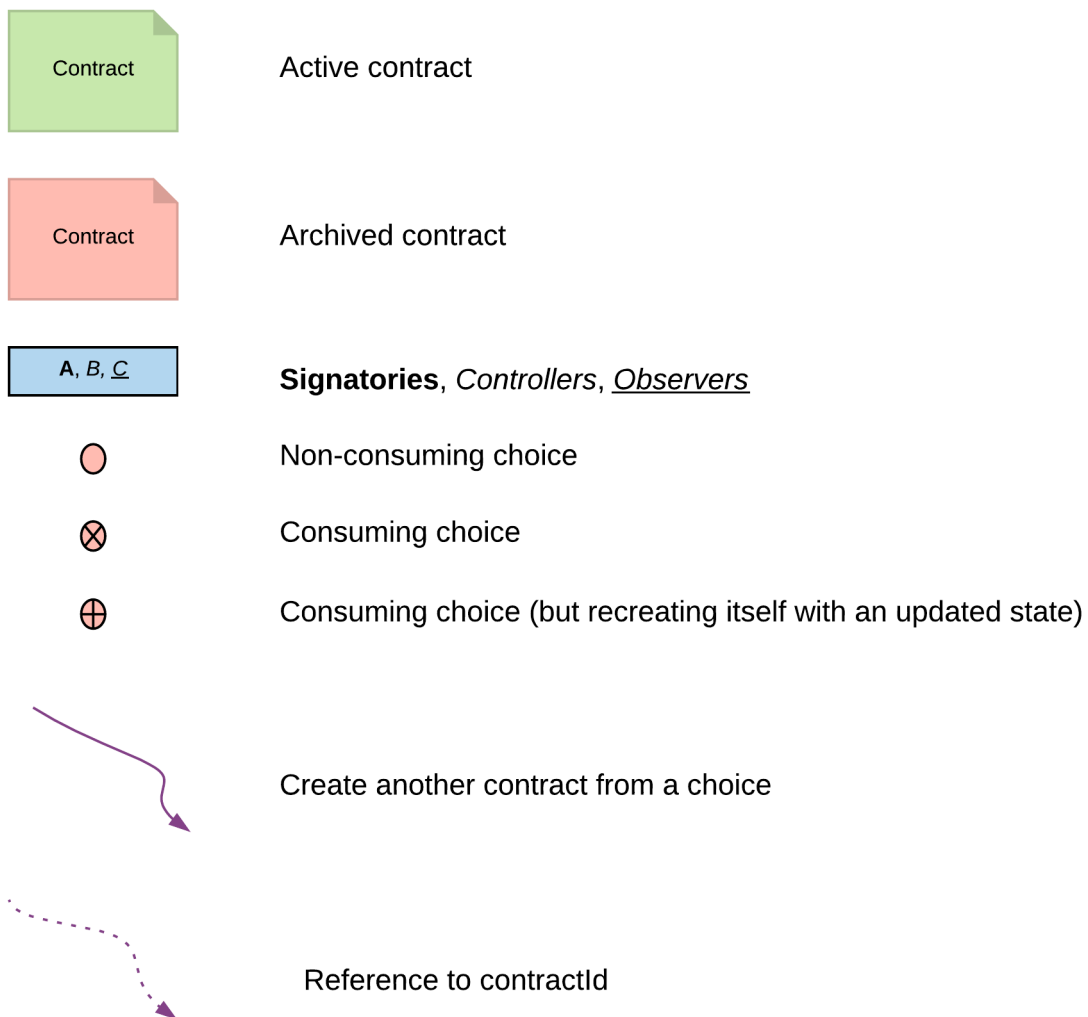

11.15 Test Daml Contracts

This chapter is all about testing and debugging the Daml contracts you’ve built using the tools from earlier chapters. You’ve already met Daml Script as a way of testing your code inside the IDE. In this chapter you’ll learn about more ways to test with Daml Script and its other uses, as well as other tools you can use for testing and debugging. You’ll also learn about a few error cases that are most likely to crop up only in actual distributed testing, and which need some care to avoid. Specifically we will cover:

- Daml Test tooling - Script, REPL, and Navigator
- Checking choice coverage
- The `trace` and `debug` functions
- Contention

Note that this section only covers testing your Daml contracts. For more holistic application testing, please refer to [Test Your App](#).

If you no longer have your projects set up, load all the code for this parts 1 and 2 of this section into two folders `intro12-part1` and `intro12-part2`, by running `daml new intro12-part1 --template daml-intro-12-part1` and `daml new intro12-part2 --template daml-intro-12-part2`.

11.15.1 Daml Test Tooling

There are three primary tools available in the SDK to test and interact with Daml contracts. It is highly recommended to explore the respective docs. The [Work with Dependencies](#) model lends itself well to being tested using these tools.

Daml Script

Daml Script should be familiar by now. It's a way to script commands and queries from multiple parties against a Daml Ledger. Unless you've browsed other sections of the documentation already, you have probably used it mostly in the IDE. However, Daml Script can do much more than that. It has four different modes of operation:

1. Run on a special Script Service in the IDE, providing the Script Views.
2. Run the Script Service via the CLI, which is useful for quick regression testing.
3. Start a Sandbox and run against that for regression testing against an actual Ledger API.
4. Run against any other already running Ledger.

Daml Navigator (Deprecated)

Daml Navigator is a UI that runs against a Ledger API and allows interaction with contracts.

Daml REPL (Deprecated)

If you want to do things interactively, Daml REPL is the tool to use. The best way to think of Daml REPL is as an interactive version of Daml Script, but it doubles up as a language REPL (Read-Evaluate-Print Loop), allowing you to evaluate pure expressions and inspect the results.

11.15.2 Debug, Trace, and Stacktraces

The above demonstrates nicely how to test the happy path, but what if a function doesn't behave as you expected? Daml has two functions that allow you to do fine-grained printf debugging: `debug` and `trace`. Both allow you to print something to `StdOut` if the code is reached. The difference between `debug` and `trace` is similar to the relationship between `abort` and `error`:

```
debug : Text -> m () maps a text to an Action that has the side-effect of printing to StdOut.  
trace : Text -> a -> a prints to StdOut when the expression is evaluated.
```

```
daml> let a : Script () = debug "foo"  
daml> let b : Script () = trace "bar" (debug "baz")  
[Daml.Script:378]: "bar"  
daml> a  
[DA.Internal.Prelude:532]: "foo"  
daml> b  
[DA.Internal.Prelude:532]: "baz"  
daml>
```

If in doubt, use `debug`. It's the easier of the two to interpret the results of.

The thing in the square brackets is the last location. It'll tell you the Daml file and line number that triggered the printing, but often no more than that because full stacktraces could violate subtrans-

action privacy quite easily. If you want to enable stacktraces for some purely functional code in your modules, you can use the machinery in [DA.Stack](#) to do so, but we won't cover that any further here.

11.15.3 Diagnose Contention Errors

The above tools and functions allow you to diagnose most problems with Daml code, but they are all synchronous. The sequence of commands is determined by the sequence of inputs. That means one of the main pitfalls of distributed applications doesn't come into play: Contention.

Contention refers to conflicts over access to contracts. Daml guarantees that there can only be one consuming choice exercised per contract so what if two parties simultaneously submit an exercise command on the same contract? Only one can succeed. Contention can also occur due to incomplete or stale knowledge. Maybe a contract was archived a little while ago, but due to latencies, a client hasn't found out yet, or maybe due to the privacy model, they never will. What all these cases have in common is that someone has incomplete knowledge of the state the ledger will be in at the time a transaction will be processed and/or committed.

For in-depth information, see the section on [Avoiding Contention](#).

If we look back at [Daml's Execution Model](#) we'll see there are three places where ledger state is read:

1. A command is submitted by some client, probably looking at the state of the ledger to build that command. Maybe the command includes references to ContractIds that the client believes are active.
2. During interpretation, ledger state is used to look up active contracts.
3. During commit, ledger state is again used to look up contracts and validate the transaction by reinterpreting it.

Collisions can occur both between 1 and 2 and between 2 and 3. Only during the commit phase is the complete relevant ledger state at the time of the transaction known, which means the ledger state at commit time is king. As a Daml contract developer, you need to understand the different causes of contention, be able to diagnose the root cause if errors of this type occur, and be able to avoid collisions by designing contracts appropriately.

11.15.3.1 Common Errors

The most common error messages you'll see are listed below. All of them can be due to one of three reasons.

1. Race Conditions - knowledge of a state change is not yet known during command submission
2. Stale References - the state change is known, but contracts have stale references to keys or ContractIds
3. Ignorance - due to privacy or operational semantics, the requester doesn't know the current state

Following the possible error messages, we'll discuss a few possible causes and remedies.

ContractId Not Found During Interpretation

```
Command interpretation error in LF-Damle: dependency error: couldn't find
↳ contract
↳ ContractId(004481eb78464f1ed3291b06504d5619db4f110df71cb5764717e1c4d3aa096b9f) .
```

ContractId Not Found During Validation

```
Disputed: dependency error: couldn't find contract ContractId
↳ (00c06fa370f8858b20fd100423d928b1d200d8e3c9975600b9c038307ed6e25d6f) .
```

fetchByKey Error During Interpretation

```
Command interpretation error in LF-Damle: dependency error: couldn't find key com.
↳ daml.lf.transaction.GlobalKey@11f4913d.
```

fetchByKey Dispute During Validation

```
Disputed: dependency error: couldn't find key com.daml.lf.transaction.
↳ GlobalKey@11f4913d
```

lookupByKey Dispute During Validation

```
Disputed: recreated and original transaction mismatch VersionedTransaction(...)
↳ expected, but VersionedTransaction(...) is recreated.
```

11.15.3.2 Avoid Race Conditions and Stale References

The first thing to avoid is write-write or write-read contention on contracts. In other words, one requester submitting a transaction with a consuming exercise on a contract while another requester submits another exercise or fetch on the same contract. This type of contention cannot be eliminated entirely, for there will always be some latency between a client submitting a command to a participant, and other clients learning of the committed transaction.

Here are a few scenarios and measures you can take to reduce this type of collision:

1. **Shard data.** Imagine you want to store a user directory on the Ledger. At the core, this is of type `[(Text, Party)]`, where `Text` is a display name and `Party` the associated Party. If you store this entire list on a single contract, any two users wanting to update their display name at the same time will cause a collision. If you instead keep each `(Text, Party)` on a separate contract, these write operations become independent from each other.

The Analogy to keep in mind when structuring your data is that a template defines a table, and a contract is a row in that table. Keeping large pieces of data on a contract is like storing big blobs in a database row. If these blobs can change through different actions, you get write conflicts.

2. Use nonconsuming choices if you can. Nonconsuming exercises have the same contention properties as fetches: they don't collide with each other.
Contract keys can seem like a way out, but they are not. Contract keys are resolved to Contract IDs during the interpretation phase on the participant node. So it reduces latencies slightly by moving resolution from the client layer to the participant layer, but it doesn't remove the issue. Going back to the auction example above, if Alice sent a command `exerciseByKey @Auction auctionKey Bid with amount = 100`, this would be resolved to an `exercise cid Bid with amount = 100` during interpretation, where `cid` is the participant's best guess what ContractId the key refers to.
3. Avoid workflows that encourage multiple parties to simultaneously try to exercise a consuming choice on the same contract. For example, imagine an `Auction` contract containing a field `highestBid : (Party, Decimal)`. If Alice tries to bid \$100 at the same time that Bob tries to bid \$90, it doesn't matter that Alice's bid is higher. The second transaction to be sequenced will be rejected as it has a write collision with the first. It's better to record the bids in separate `Bid` contracts, which can be written to independently. Again, think about how you would structure this data in a relational database to avoid data loss due to race conditions.
4. Think carefully about storing ContractIds. Imagine you had created a sharded user directory according to 1. Each user has a `User` contract that store their display name and party. Now you write a chat application where each `Message` contract refers to the sender by `ContractId User`. If the user changes their display name, that reference goes stale. You either have to modify all messages that user ever sent, or become unable to use the sender contract in Daml. If you need to be able to make this link inside Daml, Contract Keys help here. If the only place you need to link `Party` to `User` is the UI, it might be best to not store contract references in Daml at all.

11.15.3.3 Collisions Due to Ignorance

The [Daml Ledger Model](#) specifies authorization rules, and privacy rules. I.e it specifies what makes a transaction conformant, and who gets to see which parts of a committed transaction. It does *not* specify how a command is translated to a transaction. This may seem strange at first since the commands - `create`, `exercise`, `exerciseByKey`, `createAndExercise` - correspond so closely to actions in the ledger model. But the subtlety comes in on the read side. What happens when the participant, during interpretation, encounters a `fetch`, `fetchByKey`, or `lookupByKey`?

To illustrate the problem, let's assume there is a template `T` with a contract key, and Alice has witnessed two `Create` nodes of a contract of type `T` with key `k`, but no corresponding archive nodes. Alice may not be able to order these two nodes causally in the sense of "one create came before the other". See [Causality and Local Daml Ledgers](#) for an in-depth treatment of causality on Daml Ledgers.

So what should happen now if Alice's participant encounters a `fetchByKey @T k` or `lookupByKey @T k` during interpretation? What if it encounters a `fetch` node? These decisions are part of the operational semantics, and the decision of what should happen is based on the consideration that the chance of a participant submitting an invalid transaction should be minimized.

If a `fetch` or `exercise` is encountered, the participant resolves the contract as long as it has not witnessed an archive node for that contract - i.e as long as it can't guarantee that the contract is no longer active. The rationale behind this is that `fetch` and `exercise` use ContractIds, which need to come from somewhere: Command arguments, Contract arguments, or key lookups. In all three cases, someone believes the ContractId to be active still so it's worth trying.

If a `fetchByKey` or `lookupByKey` node is encountered, the contract is only resolved if the requester is a stakeholder on an active contract with the given key. If that's not the case, there is no reason to believe that the key still resolves to some contract that was witnessed earlier. Thus, when using

contract keys, make sure you make the likely requesters of transactions observers on your contracts. If you don't, `fetchByKey` will always fail, and `lookupByKey` will always return `None`.

Let's illustrate how collisions and operational semantics and interleave:

1. Bob creates `T` with key `k`. Alice is not a stakeholder.
2. Alice submits a command resulting in well-authorized `lookupByKey @T k` during interpretation. Even if Alice witnessed 1, this will resolve to a `None` as Alice is not a stakeholder. This transaction is invalid at the time of interpretation, but Alice doesn't know that.
3. Bob submits an `exerciseByKey @T k Archive`.
4. Depending on which of the transactions from 2 and 3 gets sequenced first, either just 3, or both 2 and 3 get committed. If 3 is committed before 2, 2 becomes valid while in transit.

As you can see, the behavior of `fetch`, `fetchByKey` and `lookupByKey` at interpretation time depend on what information is available to the requester at that time. That's something to keep in mind when writing Daml contracts, and something to think about when encountering frequent `Disputed` errors.

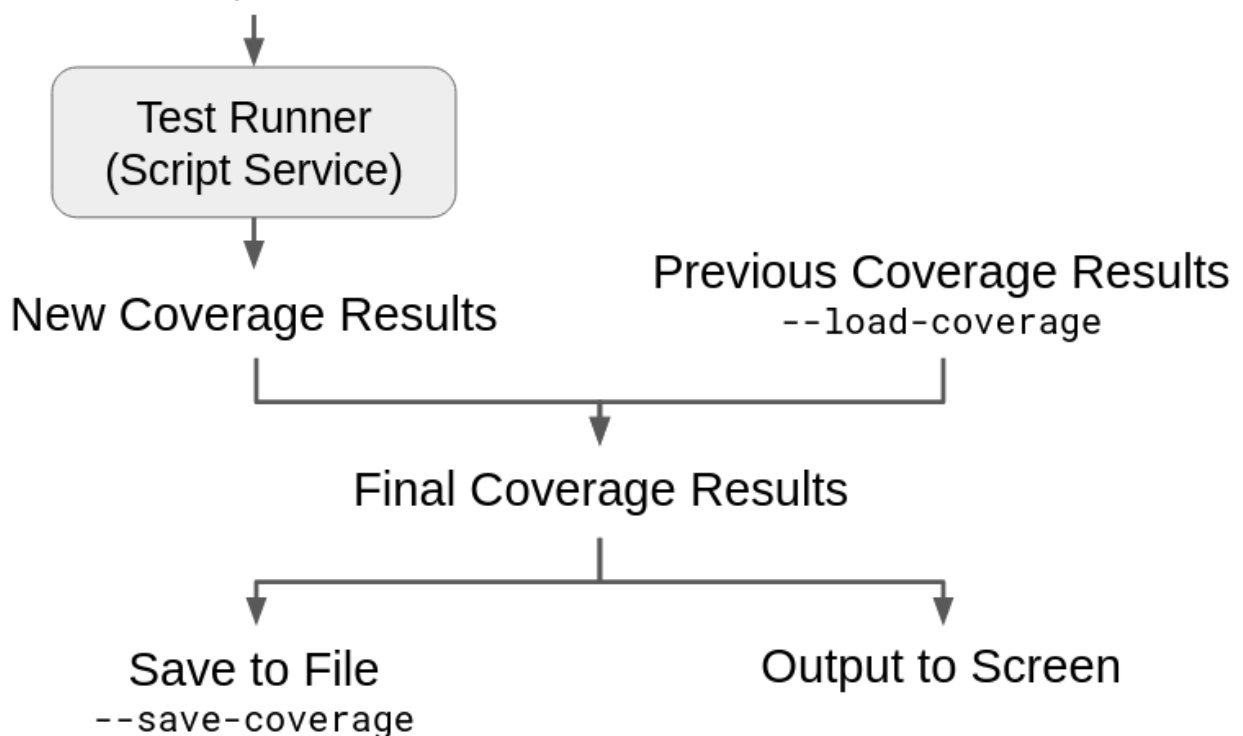

11.15.4 Checking Coverage

When `daml test` runs a set of tests, it analyzes the ledger record from those tests to report template and choice coverage. It calculates what percentage of templates defined in the package were created and what percentage of choices defined in the package were exercised.

You can also save the resulting coverage results for the test set to a file and then read them back into a future report. In an invocation of `daml test`, you can both read results in and run tests simultaneously in order to generate a final report which aggregates them. More details on the workflows that this enables are detailed in [Serializing Results Workflows](#).

Local/External Package Tests

`--all`, `--test-pattern`, `--files`

11.15.4.1 Flags Controlling Test Set

You can control the set of tests run by `daml test` using `--test-pattern PATTERN`, `--files FILE`, and `--all`.

Passing `--test-pattern <PATTERN>` runs only the local tests which match `PATTERN`.

Passing `--files <FILE>` runs only the tests found in `FILE`.

Enabling `--all` runs tests in dependency modules as well. Note: all external tests are run, regardless of the setting in `test-pattern`; `test-pattern` only restricts local tests.

11.15.4.2 Flags Controlling Serialization

You can save the final coverage results of a `daml test` invocation using `--save-coverage FILE`. This writes the list of templates and choices in scope, along with the list of templates created and choices exercised.

You can read in previous coverage results using `--load-coverage FILE`. This flag can be set multiple times, in which case the results from each file will be read and aggregated into the final result.

There may be occasions where you only need to aggregate coverage results from files, without running any tests. To do that, use the `--load-coverage-only` flag, which ensures that no tests are run.

11.15.4.3 Flags Controlling Report

Enabling `--show-coverage` tells the final printed report to include the names of any templates, choices, and interfaces which are not covered. By default, the report only reports the percentage of coverage.

You can remove choices from the rendered coverage report with `--coverage-ignore-choice PATTERN`. This flag's behavior is further documented in [Excluding Choices from the Coverage Report](#).

11.15.4.4 Define templates, choices, and interfaces

To demonstrate how the coverage report works, we start by defining three dummy templates, T1, T2, and T3. Each template has two dummy choices:

```
-- Create three dummy tokens with two dummy choices each
template T1 with owner : Party where
  signatory owner

  nonconsuming choice C_T1_1 : ()
    controller owner
    do pure ()

  nonconsuming choice C_T1_2 : ()
    controller owner
    do pure ()

template T2 with owner : Party where
  signatory owner
```

(continues on next page)

(continued from previous page)

```

nonconsuming choice C_T2_1 : ()
  controller owner
  do pure ()

nonconsuming choice C_T2_2 : ()
  controller owner
  do pure ()

template T3 with owner : Party where
  signatory owner

  nonconsuming choice C_T3_1 : ()
    controller owner
    do pure ()

  nonconsuming choice C_T3_2 : ()
    controller owner
    do pure ()

```

We also define an interface `I` with instances for `T1` and `T2`:

```

-- Create dummy interface with two dummy choices, implement over T1 and T2, and
-- an unused empty view
data IView = IView {}
interface I where
  viewtype IView
  getController : Party

  nonconsuming choice C_I_1 : ()
    controller (getController this)
    do pure ()

  nonconsuming choice C_I_2 : ()
    controller (getController this)
    do pure ()

interface instance I for T1 where
  view = IView
  getController = owner

interface instance I for T2 where
  view = IView
  getController = owner

```

11.15.4.5 Start testing

By writing a test which selectively creates and exercises only some of these templates and choices, we will see how the coverage report shows us templates and choices we haven't created and exercised respectively.

To start, the test allocates a single party, `alice`, which we will use for the whole test:

```

main = do
  -- Allocate a party

```

(continues on next page)

(continued from previous page)

```
alice <- allocateParty "Alice"
```

11.15.4.6 Template creation coverage

The coverage report mentions which templates were defined but never created. For example, the following test creates contracts out of only T1 and T2, never creating instances of template T3:

```
-- Create contracts out of templates T1 and T2
t1 <- submit alice (createCmd T1 with owner = alice)
t2 <- submit alice (createCmd T2 with owner = alice)
```

Running `daml test --show-coverage` reports how many templates were defined (3), how many were created (2, 66.7%), and the names of those that weren't created (T3):

```
> daml test --show-coverage
...
Modules internal to this package:
- Internal templates
  3 defined
  2 ( 66.7%) created
  internal templates never created: 1
    Token_Coverage_Part1:T3
...
```

11.15.4.7 Template choice exercise coverage

The coverage report also tracks which choices were exercised. For example, the following test exercises the first and second choices of T1 and the second choice of T2. It also archives T1, but not T2.

```
-- Exercise all choices & archive t1
submit alice (exerciseCmd t1 C_T1_1)
submit alice (exerciseCmd t1 C_T1_2)
submit alice (archiveCmd t1)

-- Exercise only first choice on t2, don't archive
submit alice (exerciseCmd t2 C_T2_1)
```

`daml test --show-coverage` reports that the test exercised 4 out of 9 choices, and lists the choices that weren't exercised, including the second choice of T2 and all the choices on T3.

Note that `Token_Coverage_Part1:T2:Archive` is included in the list of unexercised choices - because `t2` was not archived, its `Archive` choice was not run.

```
> daml test --show-coverage
...
- Internal template choices
  9 defined
  4 ( 44.4%) exercised
  internal template choices never exercised: 5
    Token_Coverage_Part1:T2:Archive
```

(continues on next page)

(continued from previous page)

```

Token_Coverage_Part1:T2:C_T2_2
Token_Coverage_Part1:T3:Archive
Token_Coverage_Part1:T3:C_T3_1
Token_Coverage_Part1:T3:C_T3_2
...

```

11.15.4.8 Interface choice exercise coverage

The coverage report also tracks interfaces, with two differences: * Because interfaces are not created directly but rather cast from templates which implement them, the coverage report cannot track their creation nor their archival. * Because interfaces can be cast from many possible implementing templates, the report tracks interface choices by what interface they are exercised on and which template they were cast from. In the report, these interface choices are formatted as `<module>:<template>:<choice_name>` - the `<choice_name>` tells us the interface, the `<template>` tells us the template type an interface contract was cast from.

The following test creates `t1` and `t2` as before, but casts them immediately to `I` to get two contracts of `I`: `t1_i` via `T1`, and `t2_i` via `T2`. It exercises both choices on the `t1_i`, but only the first choice on `t2_i`.

```

-- Exercise all choices on t1_i
submit alice (exerciseCmd t1_i C_I_1)
submit alice (exerciseCmd t1_i C_I_2)

-- Exercise only first choice on t2_i
submit alice (exerciseCmd t2_i C_I_1)

```

In the coverage report, there are four detected choices, as expected: two choices for the implementation of `I` for `T1`, and two choices for the implementation of `I` for `T2`. Three were exercised, so the only choice that wasn't exercised was `C_I_1` for `T2`, which is reported as `Token_Coverage_Part1:T2:C_I_1`.

```

> daml test --show-coverage
...
- Internal interface choices
  4 defined
  3 ( 75.0%) exercised
  internal interface choices never exercised: 1
    Token_Coverage_Part1:T2:C_I_1
...

```

11.15.5 Checking Coverage of External Dependencies

The coverage report also describes coverage for external templates, interfaces, and choices. In the `intro12-part1` directory, run `daml build --output intro12-part1.dar`, and copy the resulting `./intro12-part1.dar` file into the `intro12-part2` directory, where the remainder of our commands will be run.

The `daml.yaml` configuration file in `part2` specifies `intro12-part1.dar` as a dependency, letting us import its module.

11.15.5.1 Definitions

We begin by defining importing the external dependency `Token_Coverage_Part1` as `External` to bring all of its external templates and interfaces into scope.

```
import qualified Token_Coverage_Part1 as External
```

We also define a dummy template `T` with no choices, but an implementation of external interface `External.I`.

```
template T with owner: Party where
  signatory owner

  interface instance External.I for T where
    view = External.IView
    getController = owner
```

Finally, we define an interface `I` with one dummy choice, and implementations for our local template `T` and the external template `External.T1`.

```
data IView = IView {}
interface I where
  viewtype IView
  getController : Party

  nonconsuming choice I_C : ()
    controller (getController this)
    do pure ()

  interface instance I for T where
    view = IView
    getController = owner

  interface instance I for External.T1 where
    view = IView
    getController = owner
```

11.15.5.2 Local Definitions

Running `daml test -p '^$'` to create a coverage report without running any tests: Because no tests were run, coverage will be 0% in all cases. However, the report will still tally all discovered templates, interfaces, and choices, both external and internal.

```
Modules internal to this package:
- Internal templates
  1 defined
  0 ( 0.0%) created
- Internal template choices
  1 defined
  0 ( 0.0%) exercised
- Internal interface implementations
  3 defined
    2 internal interfaces
    1 external interfaces
```

(continues on next page)

(continued from previous page)

```

- Internal interface choices
  4 defined
  0 ( 0.0%) exercised

Modules external to this package:
- External templates
  3 defined
  0 ( 0.0%) created in any tests
  0 ( 0.0%) created in internal tests
  0 ( 0.0%) created in external tests
- External template choices
  9 defined
  0 ( 0.0%) exercised in any tests
  0 ( 0.0%) exercised in internal tests
  0 ( 0.0%) exercised in external tests
- External interface implementations
  2 defined
- External interface choices
  4 defined
  0 ( 0.0%) exercised in any tests
  0 ( 0.0%) exercised in internal tests
  0 ( 0.0%) exercised in external tests

```

We defined 1 template with 1 default choice (`Archive`), which get reported along with their coverage in the first two sections:

```

- Internal templates
  1 defined
  0 ( 0.0%) created
- Internal template choices
  1 defined
  0 ( 0.0%) exercised

```

We also have 3 interface implementations that we have defined locally, `External.I` for `T`, `I` for `T`, and `I` for `External.T1`. Note that while the interface implementations are local, the interfaces that they are defined over can be non-local - in this case we have 2 for the local interface `I`, and 1 for the external interface `External.I`. The total number of locally defined implementations, and the breakdown into local interfaces and external interfaces, is presented in the `Internal interface implementations` section.

```

- Internal interface implementations
  3 defined
  2 internal interfaces
  1 external interfaces

```

These local interface implementations provide 4 choices, two from `External.I` for `T`, one from `I` for `T`, and one from `I` for `External.T1`, reported in the next section along with coverage.

```

- Internal interface choices
  4 defined
  0 ( 0.0%) exercised

```

11.15.5.3 External Definitions

By importing `Token_Coverage_Part1` as `External`, we have brought 3 templates, 9 template choices, 2 interface instances, and 4 interface choices into scope from there, which are listed in the external modules section.

```
...
Modules external to this package:
- External templates
  3 defined
  ...
- External template choices
  9 defined
  ...
- External interface implementations
  2 defined
- External interface choices
  4 defined
  ...
```

11.15.5.4 External, Internal, and “Any” Coverage

Unlike internal types, externally defined types can be covered by both internal and external tests. As a result, the report for external types distinguishes between coverage provided by internal tests, external tests, and any tests (both internal and external tests).

Here we cover how to run internal and external tests simultaneously to get an aggregate report, and how to interpret this report.

The `--all` flag runs tests in external modules as well. Run `daml test --all --test-pattern notests` in the `intro12-part2` directory - this instructs `daml test` to run all tests from external modules, and to run local tests matching `notests`. We have no local tests named `notests`, so this will only run the `main` test from `part1`. Because the `main` test from `part1` does not use any of the types defined in `part2`, the internal section of the resulting coverage report shows 0% everywhere. However, the `main` test does exercise many types in `part1` which are external to `part2` - as a result, the report's `external` section is similar to the `internal` section in the report for `part1`:

```
...
Modules external to this package:
- External templates
  3 defined
  2 ( 66.7%) created in any tests
  0 ( 0.0%) created in internal tests
  2 ( 66.7%) created in external tests
- External template choices
  9 defined
  4 ( 44.4%) exercised in any tests
  0 ( 0.0%) exercised in internal tests
  4 ( 44.4%) exercised in external tests
- External interface implementations
  2 defined
- External interface choices
  4 defined
  3 ( 75.0%) exercised in any tests
```

(continues on next page)

(continued from previous page)

```
0 ( 0.0%) exercised in internal tests
3 ( 75.0%) exercised in external tests
```

Note that unlike the internal section of the report in Part 1, the external section of the report in Part 2 has coverage for internal tests, external tests, and any tests. In this report, we only ran an external test, `External:main`, so 0 is reported for all internal tests.

Let's write a local test which will create `External:T3`, a template which the `External:main` test does not create.

```
testT3 : Script ()
testT3 = do
  alice <- allocateParty "Alice"
  external_t3 <- submit alice (createCmd External.T3 with owner = alice)
  pure ()
```

If we run this test on its own using `daml test --test-pattern testT3`, our external coverage report will show that 1 out of 3 of the external templates in scope were created, 1 by internal tests and 0 by external tests.

```
...
modules external to this package:
- external templates
  3 defined
  1 ( 33.3%) created in any tests
  1 ( 33.3%) created in internal tests
  0 ( 0.0%) created in external tests
...
```

We can run this test alongside the `External:main` test using `daml test --all --test-pattern testT3`, to get an aggregate coverage report. The report now shows that 2 out of 3 of the external templates in scope were created in `External:main`, and 1 out of 3 by internal test `testT3`. Because `External:main` creates `External:T1` and `External:T2`, and `testT3` creates `External:T3`, all types are created across our tests, and the overall coverage across any tests is 3 out of 3 (100%).

```
...
Modules external to this package:
- External templates
  3 defined
  3 (100.0%) created in any tests
  1 ( 33.3%) created in internal tests
  2 ( 66.7%) created in external tests
...
```

If we define a different local test, `testT1AndT2`, which creates `T1` and `T2`, running it alongside `External:Main`, our report shows 2 out of 3 for internal tests, 2 out of 3 for external tests, but 2 out of 3 for any tests ! Because the templates created by each test overlap, `T3` is never created and never covered, so despite an abundance of testing for external templates, coverage is still less than 100%.

```
testT1AndT2 : Script ()
testT1AndT2 = do
  alice <- allocateParty "Alice"
```

(continues on next page)

(continued from previous page)

```
external_t1 <- submit alice (createCmd External.T1 with owner = alice)
external_t2 <- submit alice (createCmd External.T2 with owner = alice)
pure ()
```

```
...
Modules external to this package:
- External templates
  3 defined
  2 ( 66.7%) created in any tests
  2 ( 66.7%) created in internal tests
  2 ( 66.7%) created in external tests
...
```

External template choices and interface instance choices are also reported with any, internal, and external coverage - we will not cover them here.

11.15.5.5 Serializing Results Workflows

The `--save-coverage` and `--load-coverage` flags enable you to write coverage results to a file and read them back out again. Multiple coverage results from different files can be aggregated, along with new coverage results from tests, and then written back to a new file.

This enables three new kinds of coverage testing which should be especially useful to those with large test suites.

11.15.5.6 Single Test Iteration

When iterating on a single test, you can see the overall coverage of the system by loading in coverage results from all unchanged tests and running the single test, producing an aggregate result.

```
> # Run tests 1 through 8, long running
> daml test --pattern Test[12345678] --save-coverage unchanged-test-results
...
> # Run test 9, aggregate with results from tests 1 through 8
> daml test --pattern Test9 --load-coverage unchanged-test-results
...
> # ... make some changes to test 9 ...
> # Only need to run test 9 to compare coverage report
> daml test --pattern Test9 --load-coverage unchanged-test-results
```

11.15.5.7 Multiple Test Aggregation

When running a large test suite, you can split the suite across multiple machines and aggregate the results.

```
> # On machine 1:
> daml test --pattern Machine1Test --save-coverage machine1-results
...
> # On machine 2:
> daml test --pattern Machine2Test --save-coverage machine2-results
```

(continues on next page)

(continued from previous page)

```

...
> # On machine 3:
> daml test --pattern Machine3Test --save-coverage machine3-results
...
> # Aggregate results into a single report once all three are done
> daml test --load-coverage-only \
    --load-coverage machine1-results \
    --load-coverage machine2-results \
    --load-coverage machine3-results

```

11.15.5.8 Test Failure Recovery

If a test failure causes one `daml test` to fail, other coverage results from other tests can be used, and only the failing test needs to be rerun.

```

> # First test run
> daml test --pattern Test1 --save-coverage test1-results
...
> # Second test run:
> daml test --pattern Test2 --save-coverage test2-results
...
> # Third test run (failing):
> daml test --pattern Test3 --save-coverage test3-results
...
FAILED
...
> # ... fix third test ...
> # Third test run (succeeds):
> daml test --pattern Test3 --save-coverage test3-results
...
> # Aggregate results into a single report once all three are done
> daml test --load-coverage-only \
    --load-coverage test1-results \
    --load-coverage test2-results \
    --load-coverage test3-results

```

11.15.6 Excluding Choices from the Coverage Report

To exclude choices from the printed coverage report, use `--coverage-ignore-choice PATTERN`. Any choice whose fully qualified name matches the regular expression in `PATTERN` is removed from the coverage report. The choice will not be included in counts of defined choices or in counts of exercised choices. The choice is treated as if it does not exist.

The fully qualified name of a choice depends on whether the choice is defined in the local package or in an external package. Choices defined in the local package are fully qualified as `<module>:<template>:<choice name>`. Choices defined in external packages are fully qualified as `<package id>:<module>:<template>:<choice name>`. By defining your pattern to match different sections in the fully qualified names of your choices, you can exclude choices based on package id, module, template, or name.

11.15.6.1 Example: Excluding Archive Choices

To exclude the `Archive` choice from coverage, match for the string `Archive` in the `name` portion of the fully qualified name. Do this by specifying `--coverage-ignore-choice ':Archive$'`.

If applied to the coverage report in [Template choice exercise coverage](#), your coverage report changes from the following:

```
> daml test --show-coverage
...
- Internal template choices
9 defined
4 ( 44.4%) exercised
internal template choices never exercised: 5
  Token_Coverage_Part1:T2:Archive
  Token_Coverage_Part1:T2:C_T2_2
  Token_Coverage_Part1:T3:Archive
  Token_Coverage_Part1:T3:C_T3_1
  Token_Coverage_Part1:T3:C_T3_2
...
```

to a report that ignores `Archive` choices in all cases:

```
> daml test --show-coverage --coverage-ignore-choice ':Archive$'
...
- Internal template choices
7 defined
4 ( 57.1%) exercised
internal template choices never exercised: 3
  Token_Coverage_Part1:T2:C_T2_2
  Token_Coverage_Part1:T3:C_T3_1
  Token_Coverage_Part1:T3:C_T3_2
...
```

11.15.6.2 Example: Excluding Choices from a Specific Module

To exclude a specific module (for example `MyModule`) from coverage, match for the `module` portion of the fully qualified name. Do this by specifying `--coverage-ignore-choice ' (^|:.)MyModule:[^:]*:[^:]*$'`. This matches for any template and any choice, matches for your module name, and ignores any leading package identifier.

11.15.6.3 Excluding Choices from Serialized Reports

To ensure that serialized data always reflects full coverage information, the flag does **not** eliminate the choices from serialization using the `--save-coverage` flag. Serialized reports saved to a file always contain all information collected. The `--coverage-ignore-choice` flag only excludes choices from the printed report. For any text report generated from serialized data, you must specify `--coverage-ignore-choice` every time it is generated.

11.15.7 Next Up

There's little more to learn about writing Daml at this point that isn't best learned by practice and consulting reference material for both Daml and Haskell. In section 13, [Interfaces](#) we will cover the use of interfaces, a feature which aids code reuse across your Daml programs.

11.16 Next Steps

Now that you have completed this introduction to the Daml smart contract language, where do you go next? It depends on what you would like to do with Daml:

What you have learned so far should be enough to enable you to become a certified Daml modeler. You can test your skills at [Daml certifications](#).

If you want to improve your understanding of proven design patterns, you can learn more at [the Patterns](#) page.

If you're interested in building off-ledger services that interact and integrate with your on-ledger Daml models, read the [Building Applications](#) section.

If you're interested in understanding how to install, operate and maintain a production-grade Daml ledger, you can have a look at the [Canton user manual](#).

If you want to build Daml applications in a fully-managed environment that handles the day-to-day operation of your Daml ledger for you, you can start right away on [Daml Hub](#).

If you want to see more examples of Daml applications to understand what is possible with Daml, we have a [library full of examples](#) for you to study.

Chapter 12

Integrate Daml with Off-Ledger Services

12.1 Build Applications

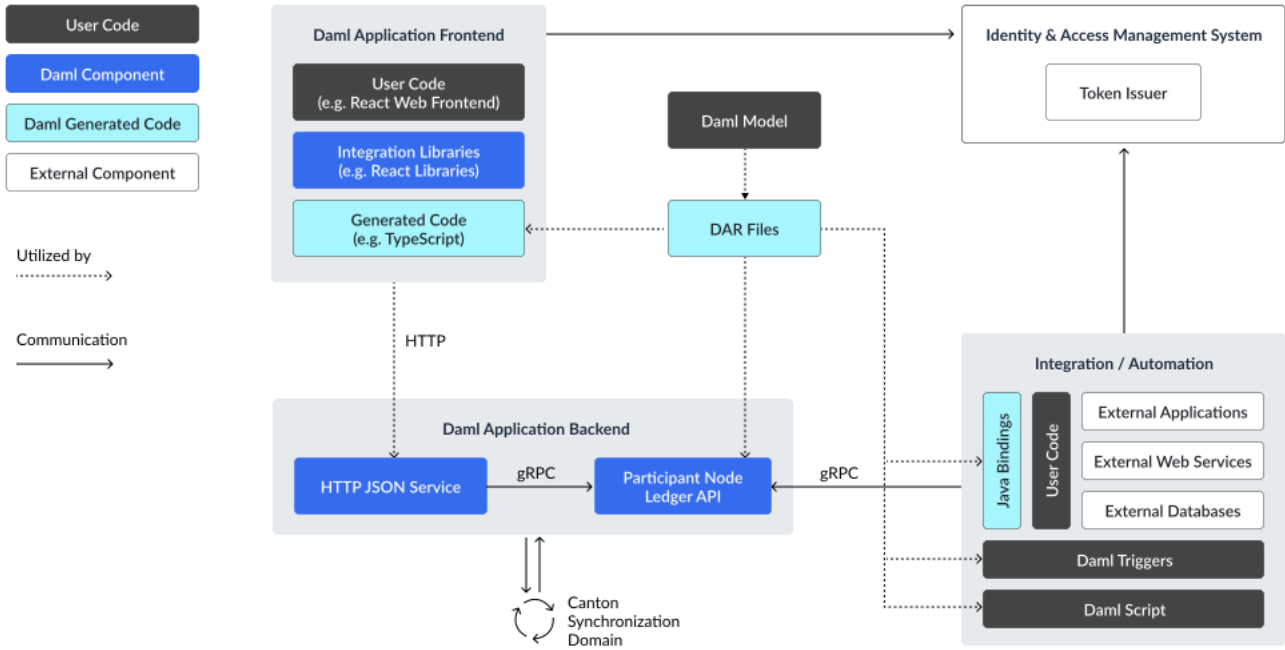

The Building Applications section covers the elements that are used to create, extend, and test your Daml full-stack application (including APIs and JavaScript client libraries) and the architectural best practices for bringing those elements together.

As with the Writing Daml section, you can find the Daml code for the example application and features [here](#) or download it using the Daml assistant. For example, to load the sources for section 1 into a folder called `intro1`, run `daml new intro1 -template daml-intro-1`.

To run the examples, you will first need to [install the Daml SDK](#).

12.2 Daml Application Architecture

This section describes our recommended design of a full-stack Daml application.

The above image shows the recommended Daml solution architecture. Here there are four types of building blocks that go into our application: user code, generated code from Daml, Daml components, and external components.

In the recommended architecture, the Daml model determines the DAR files that underpin both the front end and back end. The front end includes user code such as a React Web Frontend, Daml React libraries or other integration libraries, and generated code from the DAR files (TypeScript). A client service can access the Daml application backend instead of a GUI frontend with no change to the rest of the architecture.

From the client point of view, the Daml application backend consists of the JSON API and a participant node. The backend uses a Canton sync domain (not shown) to distribute changes to the ledger made by the application, as well as changes made by other applications, to all sync domain-connected participants.

Integrations with a Daml application are done via Java bindings. Automation can be done with Daml Script, Daml Triggers ([deprecated](#)) or a Java client. Daml Scripts allows you to write automations triggered by any off-ledger condition, such as the availability of a file in a folder, a message from a broker, or a user interacting with the system directly. Daml Triggers allow a similar approach but are triggered by on-ledger events, such as contract creation.

Daml application uses JWT tokens for access authorization, checking if the party submitting the request has the necessary rights for it. How an application acquires access tokens depends on the participant node it talks to and is ultimately set up by the participant node operator.

There are many ways that the architecture and technology stack can be changed to fit your needs, which we'll mention in the corresponding sections.

To get started quickly with the recommended application architecture, generate a new project using the `create-daml-app` template:

```
daml new --template=create-daml-app my-project-name
```

`create-daml-app` is a small, but fully functional demo application implementing the recommended architecture, providing you with an excellent starting point for your own application. It

showcases

- using Daml React libraries
- quick iteration against the [Daml Sandbox](#).
- authorization
- deploying your application in the cloud as a Docker container

12.2.1 Backend

The backend for your application can be any Daml ledger implementation running your DAR file.

We recommend using the [Daml JSON API](#) as an interface to your front end. It is served by the HTTP JSON API server connected to the ledger API server. It provides simple HTTP endpoints to interact with the ledger via GET/POST requests. However, if you prefer, you can also use the [gRPC Ledger API](#) directly.

When you use the `create-daml-app` template application, you can start a Daml Sandbox together with a JSON API server by running the following command in the root of the project.

```
daml start --start-navigator=no
```

Daml Sandbox exposes the same Daml Ledger API a Participant Node would expose without requiring a fully-fledged Daml network to back the application. Once your application matures and becomes ready for production, the `daml deploy` command helps you deploy your frontend and Daml artifacts of your project to a production Daml network.

12.2.2 Frontend

We recommended building your frontend with the [React](#) framework. However, you can choose virtually any language for your frontend and interact with the ledger via [HTTP JSON](#) endpoints. In addition, we provide support libraries for [Java](#) and you can also interact with the [gRPC Ledger API](#) directly.

We provide two libraries to build your React frontend for a Daml application.

Name	Summary
@daml/react	React hooks to query/create/exercise Daml contracts
@daml/ledger	Daml ledger object to connect and directly submit commands to the ledger

You can install any of these libraries by running `npm install <library>` in the `ui` directory of your project, e.g. `npm install @daml/react`. Please explore the `create-daml-app` example project to see the usage of these libraries.

To make your life easy when interacting with the ledger, the Daml assistant can generate JavaScript libraries with TypeScript typings from the data types declared in the deployed DAR.

```
daml codegen js .daml/dist/<your-project-name.dar> -o ui/daml.js
```

This command will generate a JavaScript library for each DALF in your DAR, containing meta-data about types and templates in the DALF and TypeScript typings them. In `create-daml-app`, `ui/package.json` refers to these libraries via the `"create-daml-app": "file:../daml.js/create-daml-app-0.1.0"` entry in the `dependencies` field.

If you choose a different JavaScript based frontend framework, the packages `@daml/ledger`, `@daml/types` and the generated `daml.js` libraries provide you with the necessary code to connect and issue commands against your ledger.

12.2.3 Authorization

When you deploy your application to a production ledger, you need to authenticate the identities of your users.

Daml ledgers support a unified interface for authorization of commands. Some Daml ledgers, like for example <https://hub.daml.com>, offer integrated authentication and authorization, but you can also use an external service provider like <https://auth0.com>. The Daml react libraries support interfacing with a Daml ledger that validates authorization of incoming requests. Simply initialize your `DamlLedger` object with the token obtained by the respective token issuer. How authorization works and the form of the required tokens is described in the [Authorization](#) section.

12.2.4 Developer Workflow

The SDK enables a local development environment with fast iteration cycles:

1. The integrated VSCode IDE (`daml studio`) runs your Scripts on any change to your Daml models. See [Daml Script](#).
2. `daml start` will build all of your Daml code, generate the JavaScript bindings, and start the required backend processes (sandbox and HTTP JSON API). It will also allow you to press `r` (followed by Enter on Windows) to rebuild your code, regenerate the JavaScript bindings and upload the new code to the running ledger.
3. `npm start` will watch your JavaScript source files for change and recompile them immediately when they are saved.

Together, these features can provide you with very tight feedback loops while developing your Daml application, all the way from your Daml contracts up to your web UI. A typical Daml developer workflow is to

1. Make a small change to your Daml data model
2. Optionally test your Daml code with [Daml Script](#)
3. Edit your React components to be aligned with changes made in Daml code
4. Extend the UI to make use of the newly introduced feature
5. Make further changes either to your Daml and/or React code until you're happy with what you've developed

See [Your First Feature](#) for a more detailed walkthrough of these steps.

12.2.4.1 Command Deduplication

The interaction of a Daml application with the ledger is inherently asynchronous: applications send commands to the ledger, and some time later they see the effect of that command on the ledger.

Several things can fail during this time window: the application can crash, the participant node can crash, messages can be lost on the network, or the ledger may be just slow to respond due to a high load.

If you want to make sure that a command is not executed twice, your application needs to robustly handle all failure scenarios. Daml ledgers provide a mechanism for [command deduplication](#) to help deal with this problem.

For each command the application provides a command ID and an optional parameter that specifies the deduplication period. If the latter parameter is not specified in the command submission itself, the ledger will use the configured maximum deduplication duration. The ledger will then guarantee that commands with the same [change ID](#) will generate a rejection within the effective deduplication period.

For details on how to use command deduplication, see the [Command Deduplication Guide](#).

12.2.4.2 Deal With Failures

Crash Recovery

In order to restart your application from a previously known ledger state, your application must keep track of the last ledger offset received from the [transaction service](#) or the [command completion service](#).

By persisting this offset alongside the relevant state as part of a single, atomic operation, your application can resume from where it left off.

Fail Over Between Ledger API Endpoints

Some Daml Ledgers support exposing multiple eventually consistent Ledger API endpoints where command deduplication works across these Ledger API endpoints. For example, these endpoints might be hosted by separate Ledger API servers that replicate the same data and host the same parties. Contact your ledger operator to find out whether this applies to your ledger.

Below we describe how you can build your application such that it can switch between such eventually consistent Ledger API endpoints to tolerate server failures. You can do this using the following two steps.

First, your application must keep track of the ledger offset as described in the [paragraph about crash recovery](#). When switching to a new Ledger API endpoint, it must resume consumption of the transaction (tree) and/or the command completion streams starting from this last received offset.

Second, your application must retry on `OUT_OF_RANGE` errors (see [gRPC status codes](#)) received from a stream subscription – using an appropriate backoff strategy to avoid overloading the server. Such errors can be raised because of eventual consistency. The Ledger API endpoint that the application is newly subscribing to might be behind the endpoint that it subscribed to before the switch, and needs time to catch up. Thanks to eventual consistency this is guaranteed to happen at some point in the future.

Once the application successfully subscribes to its required streams on the new endpoint, it will resume normal operation.

12.2.4.3 Deal With Time

The Daml language contains a function `getTime` which returns a rough estimate of current time called *Ledger Time*. The notion of time comes with a lot of problems in a distributed setting: different participants might run different clocks, there may be latencies due to calculation and network, clocks may drift against each other over time, etc.

In order to provide a useful notion of time in Daml without incurring severe performance or liveness penalties, Daml has two notions of time: *Ledger Time* and *Record Time*:

As part of command interpretation, each transaction is automatically assigned a *Ledger Time* by the participant server.

All calls to `getTime` within a transaction return the *Ledger Time* assigned to that transaction.

Ledger Time is chosen (and validated) to respect Causal Monotonicity: The Create action on a contract *c* always precedes all other actions on *c* in *Ledger Time*.

As part of the commit/synchronization protocol of the underlying infrastructure, every transaction is assigned a *Record Time*, which can be thought of as the infrastructure's system time. It's the best available notion of real time, but the only guarantees on it are the guarantees the underlying infrastructure can give. It is also not known at interpretation time.

Ledger Time is kept close to real time by bounding it against *Record Time*. Transactions where *Ledger Time* and *Record Time* are too far apart are rejected.

Some commands might take a long time to process, and by the time the resulting transaction is about to be committed to the ledger, it might violate the condition that *Ledger Time* should be reasonably close to *Record Time* (even when considering the ledger's tolerance interval). To avoid such problems, applications can set the optional parameters `min_ledger_time_abs` or `min_ledger_time_rel` that specify (in absolute or relative terms) the minimal *Ledger Time* for the transaction. The ledger will then process the command, but wait with committing the resulting transaction until *Ledger Time* fits within the ledger's tolerance interval.

How is this used in practice?

Be aware that `getTime` is only reasonably close to real time, and not completely monotonic. Avoid Daml workflows that rely on very accurate time measurements or high frequency time changes.

Set `min_ledger_time_abs` or `min_ledger_time_rel` if the duration of command interpretation and transmission is likely to take a long time relative to the tolerance interval set by the ledger.

In some corner cases, the participant node may be unable to determine a suitable *Ledger Time* by itself. If you get an error that no *Ledger Time* could be found, check whether you have contention on any contract referenced by your command or whether the referenced contracts are sensitive to small changes of `getTime`.

For more details, see [Background concepts - time](#).

12.3 Parties and Users On a Daml Ledger

Identifying parties and users is an important part of building a workable Daml application. Recall these definitions from the [Getting Started Guide](#):

Parties are unique across the entire Daml network. These must be allocated before you can use them to log in, and allocation results in a random-looking (but not actually random) string that identifies the party and is used in your Daml code. Parties are a builtin concept.

On each participant node you can create **users** with human-readable user ids. Each user can be associated with one or more parties allocated on that participant node, and refers to that party only on that node. Users are a purely local concept, meaning you can never address a user on another node by user id, and you never work with users in your Daml code; party ids are always used for these purposes. Users are also a builtin concept.

This represents a change from earlier versions of Daml, and the implications of these changes are discussed in more depth here.

12.3.1 Parties in SDK 2.0 and Subsequent

In Daml 2.0 and later versions, when you allocate a party with a given hint Alice either in the sandbox or on a production ledger you will get back a party id like `Alice::1220f2fe29866fd6a0009ecc8a64ccdc09f1958bd0f801166baaee469d1251b2eb72`.

The prefix before the double colon corresponds to the hint specified on party allocation. If the hint is not specified, it defaults to `party-${randomUUID}`. The suffix is the fingerprint of the public key that can authorize topology transactions for this party. Keys are generated randomly, so the suffix will look different locally and every time you restart Sandbox, you will get a different party id. This has a few new implications:

You can no longer allocate a party with a fixed party id. While you have some control over the prefix, we do not recommend that you rely on that to identify parties.

Party ids are no longer easily understandable by humans. You may want to display something else in your user interfaces.

Discovering the party ID of other users might get tricky. For example, to follow the user Bob, you cannot assume that their party ID is `Bob`.

12.3.2 Party ID Hints and Display Names

Party id hints and display names which existed in SDK 1.18.0 are still available in SDK 2.0.0. We recommend against relying on display names for new applications, but if you are migrating your existing application, they function exactly as before.

Party id hints still serve a purpose. While we recommend against parsing party ids and extracting the hint, for debugging and during development it can be helpful to see the party id hint at the beginning. Bear in mind that different parties can be allocated to different participants with the same party id hint. The full party ids will be different due to the suffix, but the party id hint would be the same.

The second remaining use for party id hints is to avoid duplicate party allocation. Consider sending a party allocation request that fails due to a network error. The client has no way of knowing whether the party has been allocated. Because a party allocation will be rejected if a party with the given hint already exists, the client can safely send the same request with the same hint, which will either allocate a party if the previous request failed or fail itself. (Note that while this works for Canton,

including Sandbox as well as the VMWare blockchain, it is not part of the ledger API specifications, so other ledgers might behave differently.)

12.3.3 Authorization and User Management

Daml 2.0 also introduced [user management](#). User management allows you to create users on a participant that are associated with a primary party and a dynamic set of actAs and readAs claims. Crucially, the user id can be fully controlled when creating a user – unlike party ids – and are unique on a single participant. You can also use the user id in [authorization tokens](#) instead of party tokens that have specific parties in actAs and readAs fields. This means your IAM, which can sometimes be limited in configurability, only has to work with fixed user ids.

However, users are purely local to a given participant. You cannot refer to users or parties associated with a given user on another participant via their user id. You also need admin claims to interact with the user management endpoint for users other than your own. This means that while you can have a user id in place of the primary party of your own user, you cannot generally replace party ids with user ids.

12.3.4 Working with Parties

So how do you handle these unwieldy party ids? The primary rule is to treat them as *opaque identifiers*. In particular, don't parse them, don't make assumptions about their format, and don't try to turn arbitrary strings into party ids. The only way to get a new party id is as the result of a party allocation. Applications should never hardcode specific parties. Instead either accept them as inputs or read them from contract or choice arguments.

To illustrate this, we'll go over the tools in the SDK and how this affects them:

12.3.4.1 Daml Script

In Daml script, `allocateParty` returns the party id that has been allocated. This party can then be used later, for example, in command submissions. When your script should refer to parties that have been allocated outside of the current script, accept those parties as arguments and pass them in via `-input-file`. Similarly, if your script allocates parties and you want to refer to them outside of the script, either in a later script or somewhere else, you can store them via `-output-file`. You can also query the party management and user management endpoints and get access to parties that way. Keep in mind though, this requires admin rights on a participant and there are no uniqueness guarantees for display names. That usually makes querying party and user management endpoints usually only an option for development, and we recommend passing parties as arguments where possible instead.

12.3.4.2 Daml Triggers (Deprecated)

To start a trigger via the trigger service, you still have to supply the party ids for the actAs and readAs claims for your trigger. This could, e.g., come from a party allocation in a Daml script that you wrote to a file via Daml Script's `-output-file`. Within your trigger, you get access to those parties via `getActAs` and `getReadAs`. To refer to other parties, for example when creating a contract, reference them from an existing contract. If there is no contract, consider creating a special configuration template that lists the parties your trigger should interact with outside of your trigger, and query for that template in your trigger to get access to the parties.

12.3.4.3 Navigator (Deprecated)

Navigator presents you with a list of user ids on the participant as login options. Once logged in, you will interact with the ledger as the primary party of that user. Any field that expects a party provides autocompletion, so if you know the prefix (by having chosen the hint), you don't have to remember the suffix. In addition, party ids have been shortened in the Navigator UI so that not all of the id is shown. Clicking on a party identifier will copy the full identifier to the system clipboard, making it easier to use elsewhere.

12.3.4.4 Java Bindings

When writing an application using the Java bindings, we recommend that you pass parties as arguments. They can either be CLI arguments or JVM properties as used in the `:doc: quickstart-java example <bindings-java/quickstart.html>`.

12.3.4.5 Create-daml-app and UIs

Create-daml-app and UIs in general are a bit more complex. First, they often need to interact with an IAM during the login. Second, it is often important to have human-readable names in a UI – to go back to an earlier example, a user wants to follow Bob without typing a very long party id.

Logging in is going to depend on your specific IAM, but there are a few common patterns. In create-daml-app, you log in by typing your user id directly and then interacting with the primary party of that user. In an authorized setup, users might use their email address and a password, and as a result, the IAM will provide them with a token for their user id. The approach to discovering party ids corresponding to human-readable uses can also vary depending on privacy requirements and other constraints. Create-daml-app addresses this by writing alias contracts on the ledger with associate human-readable names with the party id. These alias contracts are shared with everyone via a public party.

12.4 Access Active Contracts with the HTTP JSON API Service

12.4.1 HTTP JSON API Service

The **JSON API** provides a significantly simpler way to interact with a ledger than [the Ledger API](#) by providing *basic active contract set functionality*:

- creating contracts,
- exercising choices on contracts,
- querying the current active contract set, and
- retrieving all known parties.

The goal of this API is to get your distributed ledger application up and running quickly, so we have deliberately excluded complicating concerns including, but not limited to:

- inspecting transactions,
- asynchronous submit/completion workflows,
- temporal queries (e.g. active contracts as of a certain time), and

For these and other features, use [the Ledger API](#) instead. The HTTP JSON API service is a *proxy*, after a fashion, for that API; *there is literally nothing that HTTP JSON API service can do that your own application cannot do via gRPC*.

If you are using this API from JavaScript or TypeScript, we strongly recommend using [the JavaScript bindings and code generator](#) rather than invoking these endpoints directly. This will both simplify access to the endpoints described here and (with TypeScript) help to provide the correct JavaScript value format for each of your contracts, choice arguments, and choice results.

As suggested by those bindings, the primary target application for the HTTP JSON API service is a web application, where user actions translate to one or a few ledger operations. It is not intended for high-throughput, high-performance ledger automation; the Ledger API is better suited to such use cases.

We welcome feedback about the JSON API on [our issue tracker](#), or [on our forum](#).

12.4.1.1 Run the JSON API

Start a Daml Ledger

You can run the JSON API alongside any ledger exposing the gRPC Ledger API you want. If you don't have an existing ledger, you can start an in-memory sandbox:

```
daml new my-project --template quickstart-java
cd my-project
daml build
daml sandbox --wall-clock-time --dar ../daml/dist/quickstart-0.0.1.dar
```

Start the HTTP JSON API Service

Basic

The most basic way to start the JSON API is with the command:

```
daml json-api --config json-api-app.conf
```

where a corresponding minimal config file is

```
{
  server {
    address = "localhost"
    port = 7575
  }
  ledger-api {
    address = "localhost"
    port = 6865
  }
}
```

This will start the JSON API on port 7575 and connect it to a ledger running on `localhost:6865`.

Note: Your JSON API service should never be exposed to the internet. When running in production the JSON API should be behind a [reverse proxy, such as via NGINX](#).

The full set of configurable options that can be specified via config file is listed below

```
{
  server {
    //IP address that HTTP JSON API service listens on. Defaults to 127.0.0.1.
    address = "127.0.0.1"
    //HTTP JSON API service port number. A port number of 0 will let the system
    ↪pick an ephemeral port.
    port = 7575
  }
  ledger-api {
    address = "127.0.0.1"
    port = 6865
    tls {
      enabled = "true"
      // the certificate to be used by the server
      cert-chain-file = "cert-chain.crt"
      // private key of the server
      private-key-file = "pvt-key.pem"
      // trust collection, which means that all client certificates will be
      ↪verified using the trusted
      // certificates in this store. if omitted, the JVM default trust store is
      ↪used.
      trust-collection-file = "root-ca.crt"
    }
  }
  query-store {
```

(continues on next page)

(continued from previous page)

```

base-config {
    user = "postgres"
    password = "password"
    driver = "org.postgresql.Driver"
    url = "jdbc:postgresql://localhost:5432/test?&ssl=true"

    // prefix for table names to avoid collisions, empty by default
    table-prefix = "foo"

    // max pool size for the database connection pool
    pool-size = 12
    //specifies the min idle connections for database connection pool.
    min-idle = 4
    //specifies the idle timeout for the database connection pool.
    idle-timeout = 12s
    //specifies the connection timeout for database connection pool.
    connection-timeout = 90s
}
// option setting how the schema should be handled.
// Valid options are start-only, create-only, create-if-needed-and-start and
↪create-and-start
    start-mode = "start-only"
}

// Optional interval to poll for package updates. Examples: 500ms, 5s, 10min,
↪1h, 1d. Defaults to 5 seconds
package-reload-interval = 5s
//Optional max inbound message size in bytes. Defaults to 4194304.
max-inbound-message-size = 4194304
//Optional max inbound message size in bytes used for uploading and downloading
↪package updates. Defaults to the `max-inbound-message-size` setting.
package-max-inbound-message-size = 4194304
//Optional max cache size in entries for storing surrogate template id mappings.
↪ Defaults to None
max-template-id-cache-entries = 1000
//health check timeout in seconds
health-timeout-seconds = 5

//Optional websocket configuration parameters
websocket-config {
    //Maximum websocket session duration
    max-duration = 120m
    //Server-side heartbeat interval duration
    heartbeat-period = 5s
    //akka stream throttle-mode one of either `shaping` or `enforcing`
    mode = "shaping"
}

metrics {
    //Start a metrics reporter. Must be one of "console", "csv:///PATH",
↪"graphite://HOST[:PORT] [/METRIC_PREFIX]", or "prometheus://HOST[:PORT]".
    reporter = "console"
    //Set metric reporting interval , examples : 1s, 30s, 1m, 1h
    reporting-interval = 30s

```

(continues on next page)

(continued from previous page)

```

}

// DEV MODE ONLY (not recommended for production)
// Allow connections without a reverse proxy providing HTTPS.
allow-insecure-tokens = false
// Optional static content configuration string. Contains comma-separated key-
↪value pairs, where:
// prefix -- URL prefix,
// directory -- local directory that will be mapped to the URL prefix.
// Example: "prefix=static,directory=./static-content"
static-content {
  prefix = "static"
  directory = "static-content-dir"
}

auth-config {
  target-scope = "scope-must-be-the-same-as-in-the-participant"
}
}

```

Note: You can also start JSON API using CLI args (example below) however this is now deprecated

```
daml json-api --ledger-host localhost --ledger-port 6865 --http-port 7575
```

Standalone JAR

The `daml json-api` command is great during development since it is included with the SDK and integrates with `daml start` and other commands. Once you are ready to deploy your application, you can download the standalone JAR from [Github releases](#). It is much smaller than the whole SDK and easier to deploy since it only requires a JVM but no other dependencies and no installation process. The JAR accepts exactly the same command line parameters as `daml json-api`, so to start the standalone JAR, you can use the following command:

```
java -jar http-json-2.0.0.jar --config json-api-app.conf
```

Replace the version number `2.0.0` by the version of the SDK you are using.

With Query Store

In production setups, you should configure the HTTP JSON API service to use a PostgreSQL backend as a [Query Store](#). The in-memory backend will call the ledger to fetch the entire active contract set for the templates in your query every time so it is generally not recommended to rely on this in production. Note that the query store is a redundant copy of on-ledger data. It is safe to reinitialize the database at any time.

To enable the PostgreSQL backend you can add the `query-store` config block [as described](#).

Access Tokens

Each request to the HTTP JSON API Service *must* come with an access token, regardless of whether the underlying ledger requires it or not. This also includes development setups using an unsecured sandbox. The HTTP JSON API Service *does not* hold on to the access token, which will be only used to fulfill the request it came along with. The same token will be used to issue the request to the Ledger API.

The HTTP JSON API Service does not validate the token but may need to decode it to extract information that can be used to fill in request fields for party-specific request. How this happens depends partially on the token format you are using.

To connect to a Canton participant that uses target-scopes, the JSON API must also include target-scopes in its configuration as follows:

```
auth-config {  
    target-scope = "scope-must-be-the-same-as-in-the-participant"  
}
```

Party-specific Requests

Party-specific requests, i.e., command submissions and queries, are subject to additional restrictions. For command submissions the token must provide a proof that the bearer can act on behalf of at least one party (and possibly read on behalf of any number of parties). For queries the token must provide a proof that the bearer can either act and/or read of at least one party. This happens regardless of the used [access token format](#). The following paragraphs provide guidance as to how different token formats are used by the HTTP JSON API in this regard.

Using User Tokens

If the underlying ledger supports [user management](#) (this includes Canton and the sandbox), you are recommended to use user tokens. For command submissions, the user of the bearer should have `actAs` rights for at least one party and `readAs` rights for any number of parties. Queries require the bearer's user to have at least one `actAs` or `readAs` user right. The application id of the Ledger API request will be the user id.

Using Claim Tokens

These tokens can be used if the underlying ledger does not support [user management](#). For command submissions, `actAs` must contain at least one party and `readAs` can contain any number of parties. Queries require at least one party in either `actAs` or `readAs`. The application id is mandatory.

Note: While the JSON API receives the token it doesn't validate it itself. Upon receiving a token it will pass it, and all data contained within the request, on to the Ledger API's AuthService which will then determine if the token is valid and authorized. However, the JSON API does decode the token to extract the ledger id, application id and party so it requires that you use [a valid Daml ledger access token format](#).

For a ledger without authorization, e.g., the default configuration of Daml Sandbox, you can use <https://jwt.io> (or the JWT library of your choice) to generate your token. You can use an arbitrary secret here. The default header is fine. Under Payload, fill in:

```
{
  "https://daml.com/ledger-api": {
    "ledgerId": "sandbox",
    "applicationId": "foobar",
    "actAs": ["Alice"]
  }
}
```

The value of the `ledgerId` field has to match the `ledgerId` of your underlying Daml Ledger. For the Sandbox this corresponds to the participant id which by default is just `sandbox`.

Note: The value of `applicationId` will be used for commands submitted using that token.

The value for `actAs` is specified as a list and you provide it with the party that you want to use, such as in the example above which uses `Alice` for a party. `actAs` may include more than just one party as the JSON API supports multi-party submissions.

The party should reference an already allocated party.

Note: As mentioned above the JSON API does not validate tokens so if your ledger runs without authorization you can use an arbitrary secret.

Then the Encoded box should have your **token**, ready for passing to the service as described in the following sections.

Alternatively, here are two tokens you can use for testing:

```
{"https://daml.com/ledger-api": {"ledgerId": "sandbox", "applicationId":
"HTTP-JSON-API-Gateway", "actAs": ["Alice"]}}:
```

```
eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.
```

```
eyJodHRwczovL2RhbWwuY29tL2x1ZGdlci1hcGkiOnsibGVkZ2VySWQiOiJzYW5kYm94IiwiaXBwGljYXRpb25JZ
```

```
FIjS4ao9yulXYnv1ZL3t7ooPNiYQYAHY3pmzej4EMCM
```

```
{"https://daml.com/ledger-api": {"ledgerId": "sandbox", "applicationId":
"HTTP-JSON-API-Gateway", "actAs": ["Bob"]}}:
```

```
eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.
```

```
eyJodHRwczovL2RhbWwuY29tL2x1ZGdlci1hcGkiOnsibGVkZ2VySWQiOiJzYW5kYm94IiwiaXBwGljYXRpb25JZ
```

```
y6iwpnYt-ObtNo_FyLVxMtNTwpJF8uxzNfPELQUVKVg
```

Auth via HTTP

Set HTTP header `Authorization: Bearer paste-jwt-here`

Example:

```
Authorization: Bearer eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.  
eyJodHRwczovL2RhbWwuY29tL2x1ZGdlciilhcGkiOnsibGVkZ2VySWQiOiJNeUx1ZGdlciIsImFwcGxpY2F0aW9uS34zzF_fbWv7p60r5slkKzwndvGdsJDX-W4Xhm4oVdpk
```

Auth via WebSockets

WebSocket clients support a `subprotocols` argument (sometimes simply called `protocols`); this is usually in a list form but occasionally in comma-separated form. Check documentation for your WebSocket library of choice for details.

For HTTP JSON requests, you must pass two subprotocols:

```
daml.ws.auth  
jwt.token.paste-jwt-here
```

Example:

```
jwt.token.eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.  
eyJodHRwczovL2RhbWwuY29tL2x1ZGdlciilhcGkiOnsibGVkZ2VySWQiOiJNeUx1ZGdlciIsImFwcGxpY2F0aW9uS34zzF_fbWv7p60r5slkKzwndvGdsJDX-W4Xhm4oVdpk
```

12.4.1.2 HTTP Status Codes

The **JSON API** reports errors using standard HTTP status codes. It divides HTTP status codes into 3 groups indicating:

1. success (200)
2. failure due to a client-side problem (400, 401, 403, 404, 409, 429)
3. failure due to a server-side problem (500, 503)

The **JSON API** can return one of the following HTTP status codes:

- 200 - OK
- 400 - Bad Request (Client Error)
- 401 - Unauthorized, authentication required
- 403 - Forbidden, insufficient permissions
- 404 - Not Found
- 409 - Conflict, contract ID or key missing or duplicated
- 500 - Internal Server Error
- 503 - Service Unavailable, ledger server is not running yet or has been shut down
- 504 - Gateway Timeout, transaction failed to receive its completion within the predefined time-out

When the Ledger API returns an error code, the JSON API maps it to one of the above codes according to [the official gRPC to HTTP code mapping](#).

If a client's HTTP GET or POST request reaches an API endpoint, the corresponding response will always contain a JSON object with a `status` field, and either an `errors` or `result` field. It may also contain an optional `warnings` and/or an optional `ledgerApiError`:

```
{
  "status": <400 | 401 | 403 | 404 | 409 | 500 | 503 | 504>,
  "errors": <JSON array of strings>, | "result": <JSON object or array>,
  ["warnings": <JSON object> ],
  ["ledgerApiError": <JSON object> ]
}
```

Where:

- `status` - a JSON number which matches the HTTP response status code returned in the HTTP header,
- `errors` - a JSON array of strings, each string represents one error,
- `result` - a JSON object or JSON array, representing one or many results,
- `warnings` - an optional field with a JSON object, representing one or many warnings.
- `ledgerApiError` - an optional field with a JSON object, representing detail of an error if it was originated from Ledger API.

See the following blog post for more details about error handling best practices: [REST API Error Codes 101](#).

See [The Ledger API error codes](#) for more details about error codes from Ledger API.

Successful Response, HTTP Status: 200 OK

Content-Type: application/json
Content:

```
{
  "status": 200,
  "result": <JSON object>
}
```

Successful Response with a Warning, HTTP Status: 200 OK

Content-Type: application/json
Content:

```
{
  "status": 200,
  "result": <JSON object>,
  "warnings": <JSON object>
}
```

Failure, HTTP Status: 400 | 401 | 404 | 500

Content-Type: application/json
Content:

```
{
  "status": <400 | 401 | 404 | 500>,
  "errors": <JSON array of strings>,
  ["ledgerApiError": <JSON object> ]
}
```

Examples

Result with JSON Object without Warnings:

```
{"status": 200, "result": {...}}
```

Result with JSON Array and Warnings:

```
{"status": 200, "result": [...], "warnings": {"unknownTemplateIds": [
  ↪ "UnknownModule:UnknownEntity"]}}
```

Bad Request Error:

```
{"status": 400, "errors": ["JSON parser error: Unexpected character 'f' at input
  ↪index 27 (line 1, position 28)"]}
```

Bad Request Error with Warnings:

```
{"status":400, "errors":["Cannot resolve any template ID from request"], "warnings
  ↪":{"unknownTemplateIds":["XXX:YYY","AAA:BBB"]}}
```

Authentication Error:

```
{"status": 401, "errors": ["Authentication Required"]}
```

Not Found Error:

```
{"status": 404, "errors": ["HttpMethod(POST), uri: http://localhost:7575/v1/query1
  ↪"]}
```

Internal Server Error:

```
{"status": 500, "errors": ["Cannot initialize Ledger API"]}
```

12.4.1.3 Create a New Contract

To create an `Iou` contract from the [Quickstart guide](#):

```
template Iou
with
  issuer : Party
  owner  : Party
  currency : Text
  amount : Decimal
  observers : [Party]
```

HTTP Request

URL: `/v1/create`
 Method: POST
 Content-Type: `application/json`
 Content:

```
{
  "templateId":
  ↪ "a3b788b4dc18dc060bfb82366ae6dc055b1e361d646d5cfdb1b729607e344336:Iou:IouTransfer
  ↪ ",
  "payload": {
    "issuer": "Alice",
    "owner": "Alice",
    "currency": "USD",
    "amount": "999.99",
    "observers": []
  }
}
```

Where:

`templateId` is the contract template identifier, which has the following two formats:
`#<package name>:<module>:<entity>` or `<package ID>:<module>:<entity>`.

The package name format supports the smart contract upgrading feature, allowing contracts with different package IDs but the same package name to be used uniformly.

Using the package ID format refers to a single package.

Previously JSON API had supported partially qualified template IDs, such as simply `<module>:<entity>` as an interactive convenience which fails if there is more than one package with matching template names. **Since this format was not supported for production use and will not work with smart contract upgrades, it is now unavailable.**

`payload` field contains contract fields as defined in the Daml template and formatted according to [Daml-LF JSON Encoding](#).

HTTP Response

Content-Type: application/json
Content:

```
{
  "status": 200,
  "result": {
    "observers": [],
    "agreementText": "",
    "payload": {
      "observers": [],
      "issuer": "Alice",
      "amount": "999.99",
      "currency": "USD",
      "owner": "Alice"
    },
    "signatories": [
      "Alice"
    ],
    "contractId": "#124:0",
    "templateId":
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou",
    "completionOffset": "0000000000000084"
  }
}
```

Where:

`status` field matches the HTTP response status code returned in the HTTP header,
`result` field contains created contract details. Keep in mind that `templateId` in the **JSON API** response is always fully qualified (always contains package ID).

12.4.1.4 Create a Contract with a Command ID

When creating a new contract or exercising a choice you may specify an optional `meta` field. This allows you to control various extra settings used when submitting a command to the ledger. Each of these `meta` fields is optional.

Note: You cannot currently use `commandIds` anywhere else in the JSON API, but you can use it for observing the results of its commands outside the JSON API in logs or via the Ledger API's [Command Services](#)

```
{
  "templateId":
  ↪ "a3b788b4dc18dc060bfb82366ae6dc055b1e361d646d5cfdb1b729607e344336:Iou:IouTransfer
  ↪ ",
  "payload": {
    "observers": [],
    "issuer": "Alice",
    "amount": "999.99",
    "currency": "USD",
```

(continues on next page)

(continued from previous page)

```

    "owner": "Alice"
  },
  "meta": {
    "commandId": "a unique ID",
    "actAs": ["Alice"],
    "readAs": ["PublicParty"],
    "deduplicationPeriod": {
      "durationInMillis": 10000,
      "type": "Duration"
    },
    "submissionId": "d2f941b1-ee5c-4634-9a51-1335ce6902fa"
  }
}

```

Where:

commandId - optional field, a unique string identifying the command.

actAs - a non-empty list of parties, overriding the set from the JWT user; must be a subset of the JWT user's set.

readAs - a list of parties, overriding the set from the JWT user; must be a subset of the JWT user's set.

submissionId - a string, used for [deduplicating retried requests](#). If you do not set it, a random one will be chosen, effectively treating the request as unique and disabling deduplication.

deduplicationPeriod - either a Duration as above, which is how far back in time prior commands will be searched for this submission, or an Offset as follows, which is the earliest ledger offset after which to search for the submission.

```

"deduplicationPeriod": {
  "offset": "0000000000000000083",
  "type": "Offset"
}

```

12.4.1.5 Exercise by Contract ID

The JSON command below, demonstrates how to exercise an `Iou_Transfer` choice on an `Iou` contract:

```

choice Iou_Transfer : ContractId IouTransfer
  with
    newOwner : Party
  controller owner
  do create IouTransfer with iou = this; newOwner

```

HTTP Request

URL: /v1/exercise
Method: POST
Content-Type: application/json
Content:

```
{
  "templateId":
  ↪ "a3b788b4dc18dc060bfb82366ae6dc055b1e361d646d5cfdb1b729607e344336:Iou:IouTransfer
  ↪ ",
  "choiceInterfaceId":
  ↪ "a3b788b4dc18dc060bfb82366ae6dc055b1e361d646d5cfdb1b729607e344336:Iou:IouTransferInterfac
  ↪ ",
  "contractId": "#124:0",
  "choice": "Iou_Transfer",
  "argument": {
    "newOwner": "Alice"
  }
}
```

Where:

templateId - contract template or interface identifier, same as in [create request](#),
choiceInterfaceId - *optional* template or interface that defines the choice, same format as
templateId,
contractId - contract identifier, the value from the [create response](#),
choice - Daml contract choice, that is being exercised,
argument - contract choice argument(s).

templateId and choiceInterfaceId are treated as with [exercise by key](#). However, because contractId is always unambiguous, you may alternatively simply specify the interface ID as the templateId argument, and ignore choiceInterfaceId entirely. This isn't true of exercise-by-key or create-and-exercise, so we suggest treating this request as if this alternative isn't available.

HTTP Response

Content-Type: application/json
Content:

```
{
  "status": 200,
  "result": {
    "exerciseResult": "#201:1",
    "events": [
      {
        "archived": {
          "contractId": "#124:0",
          "templateId":
          ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou"
        }
      },
      {
        "created": {
```

(continues on next page)

(continued from previous page)

```

        "observers": [],
        "agreementText": "",
        "payload": {
            "iou": {
                "observers": [],
                "issuer": "Alice",
                "amount": "999.99",
                "currency": "USD",
                "owner": "Alice"
            },
            "newOwner": "Alice"
        },
        "signatories": [
            "Alice"
        ],
        "contractId": "#201:1",
        "templateId":
↪ "11c8f3ace75868d28136adc5cfc1cde265a9ee5ad73fe8f2db97510e3631096a2:Iou:IouTransfer
↪ "
    },
    ],
    "completionOffset": "00000000000000083"
}

```

Where:

status field matches the HTTP response status code returned in the HTTP header,

result field contains contract choice execution details:

- exerciseResult field contains the return value of the exercised contract choice.
- events contains an array of contracts that were archived and created as part of the choice execution. The array may contain: **zero or many** {"archived": {...}} and **zero or many** {"created": {...}} elements. The order of the contracts is the same as on the ledger.
- completionOffset is the ledger offset of the transaction containing the exercise's ledger changes.

12.4.1.6 Exercise by Contract Key

The JSON command below, demonstrates how to exercise the Archive choice on the Account contract with a (Party, Text) *contract key* defined like this:

```

template Account with
  owner : Party
  number : Text
  status : AccountStatus
where
  signatory owner
  key (owner, number) : (Party, Text)
  maintainer key._1

```

HTTP Request

URL: /v1/exercise
Method: POST
Content-Type: application/json
Content:

```
{
  "templateId":
  ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:Account
  ↪ ",
  "key": {
    "_1": "Alice",
    "_2": "abc123"
  },
  "choiceInterfaceId":
  ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:AccountInterface
  ↪ ",
  "choice": "Archive",
  "argument": {}
}
```

Where:

`templateId` - contract template identifier, same as in [create request](#),
`key` - contract key, formatted according to the [Daml-LF JSON Encoding](#),
`choiceInterfaceId` - *optional* template or interface that defines the choice, same format as `templateId`,
`choice` - Daml contract choice, that is being exercised,
`argument` - contract choice argument(s), empty, because `Archive` does not take any.

`key` is always searched in relation to the `templateId`. The choice, on the other hand, is searched according to `choiceInterfaceId`; if `choiceInterfaceId` is not specified, `templateId` is its default. We recommend always specifying `choiceInterfaceId` when invoking an interface choice; however, if the set of Daml-LF packages on the participant only contains one choice with a given name associated with `templateId`, that choice will be exercised, regardless of where it is defined. If a template *and* one or more of the interfaces it implements declares a choice, and `choiceInterfaceId` is not used, the one directly defined on the choice will be exercised. If choice selection is still ambiguous given these rules, the endpoint will fail as if the choice isn't defined.

HTTP Response

Formatted similar to [Exercise by Contract ID response](#).

12.4.1.7 Create and Exercise in the Same Transaction

This command allows creating a contract and exercising a choice on the newly created contract in the same transaction.

HTTP Request

URL: /v1/create-and-exercise
 Method: POST
 Content-Type: application/json
 Content:

```
{
  "templateId":
  ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou",
  "payload": {
    "observers": [],
    "issuer": "Alice",
    "amount": "999.99",
    "currency": "USD",
    "owner": "Alice"
  },
  "choiceInterfaceId":
  ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:IouInterface
  ↪ ",
  "choice": "Iou_Transfer",
  "argument": {
    "newOwner": "Bob"
  }
}
```

Where:

- templateId - the initial contract template identifier, in the same format as in the [create request](#),
- payload - the initial contract fields as defined in the Daml template and formatted according to [Daml-LF JSON Encoding](#),
- choiceInterfaceId - optional template or interface that defines the choice, same format as templateId,
- choice - Daml contract choice, that is being exercised,
- argument - contract choice argument(s).

templateId and choiceInterfaceId are treated as with [exercise by key](#), with the exception that it is payload, not key, strictly interpreted according to templateId.

HTTP Response

Please note that the response below is for a consuming choice, so it contains:

created and archived events for the initial contract ("contractId": "#1:0"), which was created and archived right away when a consuming choice was exercised on it, a created event for the contract that is the result of exercising the choice ("contractId": "#1:2").

Content-Type: application/json

Content:

```
{
  "result": {
    "exerciseResult": "#1:2",
    "events": [
      {
        "created": {
          "observers": [],
          "agreementText": "",
          "payload": {
            "observers": [],
            "issuer": "Alice",
            "amount": "999.99",
            "currency": "USD",
            "owner": "Alice"
          },
          "signatories": [

"status": 200
}

```

12.4.1.8 Fetch Contract by Contract ID

HTTP Request

URL: /v1/fetch
 Method: POST
 Content-Type: application/json
 Content:

application/json body:

```

{
  "contractId": "#201:1",
  "templateId":
↪ "a3b788b4dc18dc060bfb82366ae6dc055b1e361d646d5cfdb1b729607e344336:Iou:IouTransfer
↪ "
}

```

readers may be passed as with [Query](#). `templateId` is optional, but you are strongly advised to always pass it explicitly to minimize the data read from the Ledger API to answer the query. It can be either a template ID or an interface ID.

Contract Not Found HTTP Response

Content-Type: application/json
 Content:

```

{
  "status": 200,
  "result": null
}

```

Contract Found HTTP Response

Content-Type: application/json
Content:

```
{
  "status": 200,
  "result": {
    "observers": [],
    "agreementText": "",
    "payload": {
      "iou": {
        "observers": [],
        "issuer": "Alice",
        "amount": "999.99",
        "currency": "USD",
        "owner": "Alice"
      },
      "newOwner": "Alice"
    },
    "signatories": [

    ↪ "
  }
}
```

12.4.1.9 Fetch Contract by Key

Show the currently active contract that matches a given key.

The websocket endpoint [/v1/stream/fetch](#) can be used to search multiple keys in the same request, or in place of iteratively invoking this endpoint to respond to changes on the ledger.

HTTP Request

URL: /v1/fetch
Method: POST
Content-Type: application/json
Content:

```
{
  "templateId":
  ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:Account
  ↪ ",
  "key": {
    "_1": "Alice",
    "_2": "abc123"
  }
}
```

readers may be passed as with [Query](#).

Contract Not Found HTTP Response

Content-Type: application/json

Content:

```
{
  "status": 200,
  "result": null
}
```

Contract Found HTTP Response

Content-Type: application/json

Content:

```
{
  "status": 200,
  "result": {
    "observers": [],
    "agreementText": "",
    "payload": {
      "owner": "Alice",
      "number": "abc123",
      "status": {
        "tag": "Enabled",
        "value": "2020-01-01T00:00:01Z"
      }
    },
    "signatories": [
      "Alice"
    ],
    "key": {
      "_1": "Alice",
      "_2": "abc123"
    },
    "contractId": "#697:0",

    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:Account
    ↪ "
  }
}
```

12.4.1.10 Get All Active Contracts

List all currently active contracts for all known templates.

Note: Retrieved contracts do not get persisted into a query store database. Query store is a search index and can be used to optimize search latency. See [Start HTTP service](#) for information on how to start JSON API service with a query store enabled.

Note: You can only query active contracts with the `/v1/query` endpoint. Archived contracts (those that were archived or consumed during an exercise operation) will not be shown in the results.

HTTP Request

URL: `/v1/query`
Method: GET
Content: <EMPTY>

HTTP Response

The response is the same as for the POST method below.

12.4.1.11 Get All Active Contracts Matching a Given Query

List currently active contracts that match a given query.

The websocket endpoint `/v1/stream/query` can be used in place of iteratively invoking this endpoint to respond to changes on the ledger.

HTTP Request

URL: `/v1/query`
Method: POST
Content-Type: `application/json`
Content:

```
{
  "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou",
    "query": {"amount": 999.99},
    "readers": ["Alice"]
  ]
}
```

Where:

`templateIds` - either an array of contract template identifiers in the same format as in the [create request](#). It can also be an array containing a single interface identifier to search through.

Mixing of template ID's and interface ID's, or specifying more than one interface ID is not allowed. - `query` - search criteria to apply to the specified `templateIds`, formatted according to the [Query Language](#).

`readers` - optional non-empty list of parties to query as; must be a subset of the `actAs/readAs` parties in the JWT

Empty HTTP Response

Content-Type: application/json

Content:

```
{
  "status": 200,
  "result": []
}
```

Nonempty HTTP Response

Content-Type: application/json

Content:

```
{
  "result": [
    {
      "observers": [],
      "agreementText": "",
      "payload": {
        "observers": [],
        "issuer": "Alice",
        "amount": "999.99",
        "currency": "USD",
        "owner": "Alice"
      },
      "signatories": [
        "Alice"
      ],
      "contractId": "#52:0",
      "templateId":
↪ "b10d22d6c2f2fae41b353315cf893ed66996ecb0abe4424ea6a81576918f658a:Iou:Iou"
    },
    {
      "status": 200
    }
  ]
}
```

Where

`result` contains an array of contracts, each contract formatted according to [Daml-LF JSON Encoding](#),

`status` matches the HTTP status code returned in the HTTP header.

Nonempty HTTP Response With Unknown Template IDs Warning

Content-Type: application/json
Content:

```
{
  "warnings": {
    "unknownTemplateIds": ["UnknownModule:UnknownEntity"]
  },
  "result": [
    {
      "observers": [],
      "agreementText": "",
      "payload": {
        "observers": [],
        "issuer": "Alice",
        "amount": "999.99",
        "currency": "USD",
        "owner": "Alice"
      },
      "signatories": [
        "Alice"
      ],
      "contractId": "#52:0",
      "templateId":
↪ "b10d22d6c2f2fae41b353315cf893ed66996ecb0abe4424ea6a81576918f658a:Iou:Iou"
    }
  ],
  "status": 200
}
```

12.4.1.12 Fetch Parties by Identifiers

URL: /v1/parties
Method: POST
Content-Type: application/json
Content:

```
["Alice", "Bob", "Dave"]
```

If an empty JSON array is passed: [], this endpoint returns BadRequest(400) error:

```
{
  "status": 400,
  "errors": [
    "JsonReaderError. Cannot read JSON: <[]>. Cause: spray.json.
↪ DeserializationException: must be a list with at least 1 element"
  ]
}
```

HTTP Response

Content-Type: application/json
Content:

```
{
  "status": 200,
  "result": [
    {
      "identifier": "Alice",
      "displayName": "Alice & Co. LLC",
      "isLocal": true
    },
    {
      "identifier": "Bob",
      "displayName": "Bob & Co. LLC",
      "isLocal": true
    },
    {
      "identifier": "Dave",
      "isLocal": true
    }
  ]
}
```

Please note that the order of the party objects in the response is not guaranteed to match the order of the passed party identifiers.

Where

`identifier` - a stable unique identifier of a Daml party,
`displayName` - optional human readable name associated with the party. Might not be unique,
`isLocal` - true if party is hosted by the backing participant.

Response With Unknown Parties Warning

Content-Type: application/json
Content:

```
{
  "result": [
    {
      "identifier": "Alice",
      "displayName": "Alice & Co. LLC",
      "isLocal": true
    }
  ],
  "warnings": {
    "unknownParties": ["Erin"]
  },
  "status": 200
}
```

The `result` might be an empty JSON array if none of the requested parties is known.

12.4.1.13 Fetch All Known Parties

URL: /v1/parties
Method: GET
Content: <EMPTY>

HTTP Response

The response is the same as for the POST method above.

12.4.1.14 Allocate a New Party

This endpoint is a JSON API proxy for the Ledger API's [AllocatePartyRequest](#). For more information about party management, please refer to [Provisioning Identifiers](#) part of the Ledger API documentation.

HTTP Request

URL: /v1/parties/allocate
Method: POST
Content-Type: application/json
Content:

```
{
  "identifierHint": "Carol",
  "displayName": "Carol & Co. LLC"
}
```

Please refer to [AllocateParty](#) documentation for information about the meaning of the fields.

All fields in the request are optional, this means that an empty JSON object is a valid request to allocate a new party:

```
{ }
```

HTTP Response

```
{
  "result": {
    "identifier": "Carol",
    "displayName": "Carol & Co. LLC",
    "isLocal": true
  },
  "status": 200
}
```

12.4.1.15 Create a New User

This endpoint exposes the Ledger API's [CreateUser RPC](#).

HTTP Request

URL: /v1/user/create
Method: POST
Content-Type: application/json
Content:

```
{
  "userId": "carol",
  "primaryParty": "Carol",
  "rights": [
    {
      "type": "CanActAs",
      "party": "Carol"
    },
    {
      "type": "CanReadAs",
      "party": "Alice"
    },
    {
      "type": "CanReadAs",
      "party": "Bob"
    },
    {
      "type": "ParticipantAdmin"
    }
  ]
}
```

Please refer to [CreateUser RPC](#) documentation for information about the meaning of the fields.

Only the `userId` fields in the request is required, this means that an JSON object containing only it is a valid request to create a new user.

HTTP Response

```
{
  "result": {},
  "status": 200
}
```

12.4.1.16 Get Authenticated User Information

This endpoint exposes the Ledger API's [GetUser RPC](#).

The user ID will always be filled out with the user specified via the currently used user token.

HTTP Request

URL: /v1/user
Method: GET

HTTP Response

```
{
  "result": {
    "userId": "carol",
    "primaryParty": "Carol"
  },
  "status": 200
}
```

12.4.1.17 Get Specific User Information

This endpoint exposes the Ledger API's [GetUser RPC](#).

HTTP Request

URL: /v1/user
Method: POST
Content-Type: application/json
Content:

```
{
  "userId": "carol"
}
```

Please refer to [GetUser RPC](#) documentation for information about the meaning of the fields.

HTTP Response

```
{
  "result": {
    "userId": "carol",
    "primaryParty": "Carol"
  },
  "status": 200
}
```

12.4.1.18 Delete Specific User

This endpoint exposes the Ledger API's [DeleteUser RPC](#).

HTTP Request

URL: /v1/user/delete
Method: POST
Content-Type: application/json
Content:

```
{
  "userId": "carol"
}
```

Please refer to [DeleteUser RPC](#) documentation for information about the meaning of the fields.

HTTP Response

```
{
  "result": {},
  "status": 200
}
```

12.4.1.19 List Users

This endpoint exposes the Ledger API's [ListUsers RPC](#).

HTTP Request

URL: /v1/users
Method: GET

HTTP Response

```
{
  "result": [
    {
      "userId": "carol",
      "primaryParty": "Carol"
    },
    {
      "userId": "bob",
      "primaryParty": "Bob"
    }
  ],
  "status": 200
}
```

12.4.1.20 Grant User Rights

This endpoint exposes the Ledger API's [GrantUserRights RPC](#).

HTTP Request

URL: /v1/user/rights/grant
Method: POST
Content-Type: application/json
Content:

```
{
  "userId": "carol",
  "rights": [
    {
      "type": "CanActAs",
      "party": "Carol"
    },
    {
      "type": "CanReadAs",
      "party": "Alice"
    },
    {
      "type": "CanReadAs",
      "party": "Bob"
    },
    {
      "type": "ParticipantAdmin"
    }
  ]
}
```

Please refer to [GrantUserRights RPC](#) documentation for information about the meaning of the fields.

HTTP Response

```
{
  "result": [
    {
      "type": "CanActAs",
      "party": "Carol"
    },
    {
      "type": "CanReadAs",
      "party": "Alice"
    },
    {
      "type": "CanReadAs",
      "party": "Bob"
    },
    {
      "type": "ParticipantAdmin"
    }
  ],
  "status": 200
}
```

Returns the rights that were newly granted.

12.4.1.21 Revoke User Rights

This endpoint exposes the Ledger API's [RevokeUserRights RPC](#).

HTTP Request

URL: /v1/user/rights/revoke
 Method: POST
 Content-Type: application/json
 Content:

```
{
  "userId": "carol",
  "rights": [
    {
      "type": "CanActAs",
      "party": "Carol"
    },
    {
      "type": "CanReadAs",
      "party": "Alice"
    },
    {
      "type": "CanReadAs",
      "party": "Bob"
    },
    {
      "type": "ParticipantAdmin"
    }
  ]
}
```

(continues on next page)

(continued from previous page)

```
}  
]  
}
```

Please refer to [RevokeUserRights RPC](#) documentation for information about the meaning of the fields.

HTTP Response

```
{  
  "result": [  
    {  
      "type": "CanActAs",  
      "party": "Carol"  
    },  
    {  
      "type": "CanReadAs",  
      "party": "Alice"  
    },  
    {  
      "type": "CanReadAs",  
      "party": "Bob"  
    },  
    {  
      "type": "ParticipantAdmin"  
    }  
  ],  
  "status": 200  
}
```

Returns the rights that were actually granted.

12.4.1.22 List Authenticated User Rights

This endpoint exposes the Ledger API's [ListUserRights RPC](#).

The user ID will always be filled out with the user specified via the currently used user token.

HTTP Request

URL: /v1/user/rights
Method: GET

HTTP Response

```
{
  "result": [
    {
      "type": "CanActAs",
      "party": "Carol"
    },
    {
      "type": "CanReadAs",
      "party": "Alice"
    },
    {
      "type": "CanReadAs",
      "party": "Bob"
    },
    {
      "type": "ParticipantAdmin"
    }
  ],
  "status": 200
}
```

12.4.1.23 List Specific User Rights

This endpoint exposes the Ledger API's [ListUserRights RPC](#).

HTTP Request

URL: /v1/user/rights
 Method: POST
 Content-Type: application/json
 Content:

```
{
  "userId": "carol"
}
```

Please refer to [ListUserRights RPC](#) documentation for information about the meaning of the fields.

HTTP Response

```
{
  "result": [
    {
      "type": "CanActAs",
      "party": "Carol"
    },
    {
      "type": "CanReadAs",
```

(continues on next page)

(continued from previous page)

```
    "party": "Alice"
  },
  {
    "type": "CanReadAs",
    "party": "Bob"
  },
  {
    "type": "ParticipantAdmin"
  }
],
"status": 200
}
```

12.4.1.24 List All DALF Packages

HTTP Request

URL: /v1/packages
Method: GET
Content: <EMPTY>

HTTP Response

```
{
  "result": [
    "c1f1f00558799eec139fb4f4c76f95fb52fa1837a5dd29600baa1c8ed1bdccfd",
    "733e38d36a2759688a4b2c4cec69d48e7b55ecc8dedc8067b815926c917a182a",
    "bfcd37bd6b84768e86e432f5f6c33e25d9e7724a9d42e33875ff74f6348e733f",
    "40f452260bef3f29dede136108fc08a88d5a5250310281067087da6f0baddff7",
    "8a7806365bbd98d88b4c13832ebfa305f6abaeaf32cfa2b7dd25c4fa489b79fb"
  ],
  "status": 200
}
```

Where `result` is the JSON array containing the package IDs of all loaded DALFs.

12.4.1.25 Download a DALF Package

HTTP Request

URL: /v1/packages/<package ID>
Method: GET
Content: <EMPTY>

Note that the desired package ID is specified in the URL.

HTTP Response, status: 200 OK

Transfer-Encoding: chunked
Content-Type: application/octet-stream
Content: <DALF bytes>

The content (body) of the HTTP response contains raw DALF package bytes, without any encoding. Note that the package ID specified in the URL is actually the SHA-256 hash of the downloaded DALF package and can be used to validate the integrity of the downloaded content.

HTTP Response With Error, Any Status Different from 200 OK

Any status different from 200 OK will be in the format specified below.

Content-Type: application/json
Content:

```
{
  "errors": [
    "io.grpc.StatusRuntimeException: NOT_FOUND"
  ],
  "status": 500
}
```

12.4.1.26 Upload a DAR File

HTTP Request

URL: /v1/packages
Method: POST
Content-Type: application/octet-stream
Content: <DAR bytes>

The content (body) of the HTTP request contains raw DAR file bytes, without any encoding.

HTTP Response, Status: 200 OK

Content-Type: application/json
Content:

```
{
  "result": 1,
  "status": 200
}
```

HTTP Response With Error

Content-Type: application/json
Content:

```
{
  "errors": [
    "io.grpc.StatusRuntimeException: INVALID_ARGUMENT: Invalid argument:↵
    ↵Invalid DAR: package-upload, content: []]"
  ],
  "status": 500
}
```

12.4.1.27 Metering Report

For a description of participant metering, the parameters, and the report format see the [Participant Metering](#).

URL: /v1/metering-report
Method: POST
Content-Type: application/json
Content:

```
{
  "from": "2022-01-01",
  "to": "2022-02-01",
  "application": "some-application"
}
```

HTTP Response

Content-Type: application/json
Content:

```
{
  "status": 200,
  "result": {
    "participant": "some-participant",
    "request": {
      "from": "2022-01-01T00:00:00Z",
      "to": "2022-02-01T00:00:00Z"
    },
    "final": true,
    "applications": [
      {
        "application": "some-application",
        "events": 42
      }
    ]
  }
}
```

(continued from previous page)

```

    "status":400
  }

  {
    "errors":["Could not resolve any template ID from request."],
    "status":400
  }

```

Contracts Query Stream

URL: /v1/stream/query

Scheme: ws

Protocol: WebSocket

List currently active contracts that match a given query, with continuous updates.

Simpler use-cases that do not require continuous updates should use the simpler [/v1/query](#) endpoint instead.

application/json body must be sent first, formatted according to the [Query Language](#):

```

{ "templateIds": [
  ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou" ] }

```

Multiple queries may be specified in an array, for overlapping or different sets of template IDs:

```

[
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou" ],
    ↪ "query": { "amount": { "%lte": 50 } } },
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:OtherIou:OtherIou" ],
    ↪ "query": { "amount": { "%gt": 50 } } },
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou" ] }
]

```

Only one interface ID can be provided in `templateIds`. An interface ID can be used in all queries:

```

[
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Ifc:Ifc" ],
    ↪ "query": { "amount": { "%lte": 50 } } },
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Ifc:Ifc" ],
    ↪ "query": { "amount": { "%gt": 50 } } },
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Ifc:Ifc" ] }
]

```

Mixing of template ID's and interface ID's or specifying more than one interface ID across queries is not allowed. BadRequest(400) error will be returned.:

```
[
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou" ],
    ↪ "query": { "amount": { "%lte": 50 } } },
    { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Ifc:Ifc" ],
    ↪ "query": { "amount": { "%gt": 50 } } },
    { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Ifc:Ifc" ] }
]
```

Queries have two ways to specify an offset.

An `offset`, a string supplied by an earlier query output message, may optionally be specified alongside each query itself:

```
[
  { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou" ],
    ↪ "query": { "amount": { "%lte": 50 } } },
    { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou" ],
    ↪ "query": { "amount": { "%gt": 50 } } },
    { "templateIds": [
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Iou:Iou" ],
    ↪ "offset": "5609" }
]
```

If specified, the stream will include only contract creations and archivals *after* the response body that included that offset. Queries with no offset will begin with all active contracts for that query, as usual.

If an offset is specified *before* the queries, as a separate body, it will be used as a default offset for all queries that do not include an offset themselves:

```
{ "offset": "4307" }
```

For example, if this message preceded the above 3-query example, it would be as if "4307" had been specified for the first two queries, while "5609" would be used for the third query.

If any offset has been pruned, the websocket will immediately fail with code 1011 and message `internal error`.

The output is a series of JSON documents, each `payload` formatted according to [Daml-LF JSON Encoding](#):

```
{
  "events": [{
    "created": {
      "observers": [],
      "agreementText": "",
      "payload": {
        "observers": [],
        "issuer": "Alice",
        "amount": "999.99",
        "currency": "USD",
```

(continues on next page)

(continued from previous page)

```

        "owner": "Alice"
      },
      "signatories": ["Alice"],
      "contractId": "#1:0",
      "templateId":
↪ "eb3b150383a979d6765b8570a17dd24ae8d8b63418ee5fd20df20ad2a1c13976:Iou:Iou"
    },
    "matchedQueries": [1, 2]
  ]
}

```

where `matchedQueries` indicates the 0-based indices into the request list of queries that matched this contract.

Every `events` block following the end of contracts that existed when the request started includes an `offset`. The stream is guaranteed to send an `offset` immediately at the beginning of this `live` data, which may or may not contain any `events`; if it does not contain events and no events were emitted before, it may be `null` if there was no transaction on the ledger or a string representing the current ledger end; otherwise, it will be a string. For example, you might use it to turn off an initial loading indicator:

```

{
  "events": [],
  "offset": "2"
}

```

Note: Events in the following `live` data may include `events` that precede this `offset` if an earlier per-query `offset` was specified.

This has been done with the intent of allowing to use per-query `offset`s to efficiently use a single connection to multiplex various requests. To give an example of how this would work, let's say that there are two contract templates, `A` and `B`. Your application first queries for `A`s without specifying an `offset`. Then some client-side interaction requires the application to do the same for `B`s. The application can save the latest observed `offset` for the previous query, which let's say is 42, and issue a new request that queries for all `B`s without specifying an `offset` and all `A`s from 42. While this happens on the client, a few more `A`s and `B`s are created and the new request is issued once the latest `offset` is 47. The response to this will contain a message with all active `B`s, followed by the message reporting the `offset` 47, followed by a stream of live updates that contains new `A`s starting from 42 and new `B`s starting from 47.

To keep the stream alive, you'll occasionally see messages like this, which can be safely ignored if you do not need to capture the last seen ledger `offset`:

```

{"events": [], "offset": "5609"}

```

where `offset` is the last seen ledger `offset`.

After submitting an `Iou_Split` exercise, which creates two contracts and archives the one above, the same stream will eventually produce:

```

{
  "events": [{

```

(continues on next page)

(continued from previous page)

```

    "archived": {
      "contractId": "#1:0",
      "templateId":
↪ "eb3b150383a979d6765b8570a17dd24ae8d8b63418ee5fd20df20ad2a1c13976:Iou:Iou"
    }, {
      "created": {
        "observers": [],
        "agreementText": "",
        "payload": {
          "observers": [],
          "issuer": "Alice",
          "amount": "42.42",
          "currency": "USD",
          "owner": "Alice"
        },
        "signatories": ["Alice"],
        "contractId": "#2:1",
        "templateId":
↪ "eb3b150383a979d6765b8570a17dd24ae8d8b63418ee5fd20df20ad2a1c13976:Iou:Iou"
      },
      "matchedQueries": [0, 2]
    }, {
      "created": {
        "observers": [],
        "agreementText": "",
        "payload": {
          "observers": [],
          "issuer": "Alice",
          "amount": "957.57",
          "currency": "USD",
          "owner": "Alice"
        },
        "signatories": ["Alice"],
        "contractId": "#2:2",
        "templateId":
↪ "eb3b150383a979d6765b8570a17dd24ae8d8b63418ee5fd20df20ad2a1c13976:Iou:Iou"
      },
      "matchedQueries": [1, 2]
    }
  ],
  "offset": "3"
}

```

If any template IDs are found not to resolve, the first element of the stream will report them:

```
{ "warnings": { "unknownTemplateIds": ["UnknownModule:UnknownEntity"] } }
```

and the stream will continue, provided that at least one template ID resolved properly.

Aside from "created" and "archived" elements, "error" elements may appear, which contain a string describing the error. The stream will continue in these cases, rather than terminating.

Some notes on behavior:

1. Each result array means this is what would have changed if you just polled `/v1/query` iteratively. In particular, just as polling search can miss contracts (as a create and archive can be paired between polls), such contracts may or may not appear in any result object.

2. No `archived` ever contains a contract ID occurring within a `created` in the same array. So, for example, supposing you are keeping an internal map of active contracts keyed by contract ID, you can apply the `created` first or the `archived` first, forwards, backwards, or in random order, and be guaranteed to get the same results.
3. Within a given array, if an `archived` and `created` refer to contracts with the same template ID and [contract key](#), the `archived` is guaranteed to occur before the `created`.
4. Except in cases of #3, within a single response array, the order of `created` and `archived` is undefined and does not imply that any element occurred before or after any other one.
5. You will almost certainly receive contract IDs in `archived` that you never received a `created` for. These are contracts that query filtered out, but for which the server no longer is aware of that. You can safely ignore these. However, such `phantom archives` are guaranteed to represent an actual archival *on the ledger*, so if you are keeping a more global dataset outside the context of this specific search, you can use that archival information as you wish.

Fetch by Key Contracts Stream

URL: `/v1/stream/fetch`
Scheme: `ws`
Protocol: `WebSocket`

List currently active contracts that match one of the given `{templateId, key}` pairs, with continuous updates.

Simpler use-cases that search for only a single key and do not require continuous updates should use the simpler [/v1/fetch](#) endpoint instead.

`application/json` body must be sent first, formatted according to the following rule:

```
[
  {"templateId": "<template ID 1>", "key": <key 1>},
  {"templateId": "<template ID 2>", "key": <key 2>},
  ...
  {"templateId": "<template ID N>", "key": <key N>}
]
```

Where:

`templateId` - contract template identifier, same as in [create request](#),
`key` - contract key, formatted according to the [Daml-LF JSON Encoding](#),

Example:

```
[
  {"templateId":
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:Account",
    ↪ "key": {"_1": "Alice", "_2": "abc123"}},
  {"templateId":
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:Account",
    ↪ "key": {"_1": "Alice", "_2": "def345"}}
]
```

The output stream has the same format as the output from the [Contracts Query Stream](#). We further guarantee that for every `archived` event appearing on the stream there has been a matching `created` event earlier in the stream, except in the case of missing `contractIdAtOffset` fields in the case described below.

You may supply optional `offset`s for the stream, exactly as with query streams. However, you should supply with each `{templateId, key}` pair a `contractIdAtOffset`, which is the contract ID currently associated with that pair at the point of the given offset, or `null` if no contract ID was associated with the pair at that offset. For example, with the above keys, if you had one "abc123" contract but no "def345" contract, you might specify:

```
[
  {
    "templateId":
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:Account",
    ↪ "key": { "_1": "Alice", "_2": "abc123" },
    "contractIdAtOffset": "#1:0" },
  {
    "templateId":
    ↪ "11c8f3ace75868d28136adc5cfc1de265a9ee5ad73fe8f2db97510e3631096a2:Account:Account",
    ↪ "key": { "_1": "Alice", "_2": "def345" },
    "contractIdAtOffset": null }
]
```

If every `contractIdAtOffset` is specified, as is so in the example above, you will not receive any archived events for contracts created before the offset unless those contracts are identified in a `contractIdAtOffset`. By contrast, if any `contractIdAtOffset` is missing, archived event filtering will be disabled, and you will receive phantom archives as with query streams.

12.4.1.29 Healthcheck Endpoints

The HTTP JSON API provides two healthcheck endpoints for integration with schedulers like [Kubernetes](#).

Liveness Check

URL: `/livez`
Method: GET

A status code of 200 indicates a successful liveness check.

This is an unauthenticated endpoint intended to be used as a liveness probe.

Readiness Check

URL: `/readyz`
Method: GET

A status code of 200 indicates a successful readiness check.

This is an unauthenticated endpoint intended to be used as a readiness probe. It validates both the ledger connection as well as the database connection.

12.4.2 Daml-LF JSON Encoding

We describe how to decode and encode Daml-LF values as JSON. For each Daml-LF type we explain what JSON inputs we accept (decoding), and what JSON output we produce (encoding).

If you use [the JavaScript code generator](#) with TypeScript, the generated types for templates and choices will incorporate the following automatically. You can use this to observe how these rules apply to your templates, or ignore this document and rely on the TypeScript type checker to tell you how to encode data for JSON API correctly.

12.4.2.1 Codec Library

At the library level, the output format is parameterized by two flags:

```
encodeDecimalAsString: boolean  
encodeInt64AsString: boolean
```

The suggested defaults for both of these flags is false. If the intended recipient is written in JavaScript, however, note that the JavaScript data model will decode these as numbers, discarding data in some cases; `encode-as-String` avoids this, as mentioned with respect to `JSON.parse` below. **For that reason, the HTTP JSON API Service uses `true` for both flags.**

12.4.2.2 Type-directed Parsing

Note that throughout the document the decoding is type-directed. In other words, the same JSON value can correspond to many Daml-LF values, and a single Daml-LF value can correspond to multiple JSON encodings. This means it is crucial to know the expected type of a JSON-encoded LF value to make sense of it.

For that reason, you should parse the data into appropriate data types (including parsing numbers into appropriate representations) before doing any meaningful manipulations (e.g. comparison for equality).

12.4.2.3 ContractId

Contract ids are expressed as their string representation:

```
"123"  
"XYZ"  
"foo:bar#baz"
```

12.4.2.5 Int64

Input

Int64, much like Decimal, can be represented as JSON numbers and as strings, with the string representation being `[+-]?[0-9]+`. The numbers must fall within `[-9223372036854775808, 9223372036854775807]`. Moreover, if represented as JSON numbers, they must have no fractional part.

A few valid examples:

```
42
"+42"
-42
0
-0
9223372036854775807
"9223372036854775807"
-9223372036854775808
"-9223372036854775808"
```

A few invalid examples:

```
42.3
+42
9223372036854775808
-9223372036854775809
"garbage"
"  42  "
```

Output

If `encodeInt64AsString` is set, Int64s are encoded as strings, using the format `-?[0-9]+`. If `encodeInt64AsString` is not set, they are encoded as JSON numbers, also using the format `-?[0-9]+`.

Note that the flag `encodeInt64AsString` is useful because it lets JavaScript consumers consume Int64s safely with the standard `JSON.parse`.

12.4.2.6 Timestamp

Input

Timestamps are represented as ISO 8601 strings, rendered using the format `yyyy-mm-ddThh:mm:ss.ssssssZ`:

```
1990-11-09T04:30:23.123456Z
9999-12-31T23:59:59.999999Z
```

Parsing is a little bit more flexible and uses the format `yyyy-mm-ddThh:mm:ss(\.s+)?Z`, i.e. it's OK to omit the microsecond part partially or entirely, or have more than 6 decimals. Sub-second data beyond microseconds will be dropped. The UTC timezone designator must be included. The

rationale behind the inclusion of the timezone designator is minimizing the risk that users pass in local times. Valid examples:

```
1990-11-09T04:30:23.1234569Z
1990-11-09T04:30:23Z
1990-11-09T04:30:23.123Z
0001-01-01T00:00:00Z
9999-12-31T23:59:59.9999999Z
```

The timestamp must be between the bounds specified by Daml-LF and ISO 8601, [0001-01-01T00:00:00Z, 9999-12-31T23:59:59.9999999Z].

Notes:

When using Java 11, valid ISO 8601 timestamp strings with a TimeZone offset (e.g. 2016-09-12T16:45:51+01:00) are rejected due to [JDK-8166138: DateTimeFormatter.ISO_INSTANT should handle offsets](#).

When using Java 17+, all valid ISO 8601 timestamp strings can be parsed and so accepted.

JavaScript

```
> new Date().toISOString()
'2019-06-18T08:59:34.191Z'
```

Python

```
>>> datetime.datetime.utcnow().isoformat() + 'Z'
'2019-06-18T08:59:08.392764Z'
```

Java

```
import java.time.Instant;
class Main {
    public static void main(String[] args) {
        Instant instant = Instant.now();
        // prints 2019-06-18T09:02:16.652Z
        System.out.println(instant.toString());
    }
}
```

Output

Timestamps are encoded as ISO 8601 strings, rendered using the format `yyyy-mm-ddThh:mm:ss[.sssss]Z`.

The sub-second part will be formatted as follows:

- If no sub-second part is present in the timestamp (i.e. the timestamp represents whole seconds), the sub-second part will be omitted entirely;
- If the sub-second part does not go beyond milliseconds, the sub-second part will be up to milliseconds, padding with trailing 0s if necessary;
- Otherwise, the sub-second part will be up to microseconds, padding with trailing 0s if necessary.

In other words, the encoded timestamp will either have no sub-second part, a sub-second part of length 3, or a sub-second part of length 6.

12.4.2.7 Party

Represented using their string representation, without any additional quotes:

```
"Alice"  
"Bob"
```

12.4.2.8 Unit

Represented as empty object `{}`. Note that in JavaScript `{}` `!== {}`; however, `null` would be ambiguous; for the type `Optional Unit`, `null` decodes to `None`, but `{}` decodes to `Some {}`.

Additionally, we think that this is the least confusing encoding for `Unit` since `unit` is conceptually an empty record. We do not want to imply that `Unit` is used similarly to `null` in JavaScript or `None` in Python.

12.4.2.9 Date

Represented as an ISO 8601 date rendered using the format `yyyy-mm-dd`:

```
2019-06-18  
9999-12-31  
0001-01-01
```

The dates must be between the bounds specified by Daml-LF and ISO 8601, [0001-01-01, 9999-12-31].

12.4.2.10 Text

Represented as strings.

12.4.2.11 Bool

Represented as booleans.

12.4.2.12 Record

Input

Records can be represented in two ways. As objects:

```
{ f1: v1, ..., fn: vn }
```

And as arrays:

```
[ v1, ..., vn ]
```

Note that Daml-LF record fields are ordered. So if we have

```
record Foo = {f1: Int64, f2: Bool}
```

when representing the record as an array the user must specify the fields in order:

```
[42, true]
```

The motivation for the array format for records is to allow specifying tuple types closer to what it looks like in Daml. Note that a Daml tuple, i.e. (42, True), will be compiled to a Daml-LF record `Tuple2 { _1 = 42, _2 = True }`.

Output

Records are always encoded as objects.

12.4.2.13 List

Lists are represented as

```
[v□, ..., v□]
```

12.4.2.14 TextMap

TextMaps are represented as objects:

```
{ k□: v□, ..., k□: v□ }
```

12.4.2.15 GenMap

GenMaps are represented as lists of pairs:

```
[ [k□, v□], [k□, v□] ]
```

Order does not matter. However, any duplicate keys will cause the map to be treated as invalid.

12.4.2.16 Optional

Input

Optionals are encoded using `null` if the value is `None`, and with the value itself if it's `Some`. However, this alone does not let us encode nested optionals unambiguously. Therefore, nested Optionals are encoded using an empty list for `None`, and a list with one element for `Some`. Note that after the top-level Optional, all the nested ones must be represented using the list notation.

A few examples, using the form

```
JSON --> Daml-LF : Expected Daml-LF type
```

to make clear what the target Daml-LF type is:

```

null    --> None                : Optional Int64
null    --> None                : Optional (Optional Int64)
42      --> Some 42                : Optional Int64
[]       --> Some None           : Optional (Optional Int64)
[42]    --> Some (Some 42)        : Optional (Optional Int64)
[[]]    --> Some (Some None)     : Optional (Optional (Optional Int64))
[[42]]  --> Some (Some (Some 42)) : Optional (Optional (Optional Int64))
...

```

Finally, if `Optional` values appear in records, they can be omitted to represent `None`. Given Daml-LF types

```

record Depth1 = { foo: Optional Int64 }
record Depth2 = { foo: Optional (Optional Int64) }

```

We have

```

{ }           --> Depth1 { foo: None }           : Depth1
{ }           --> Depth2 { foo: None }           : Depth2
{ foo: 42 }    --> Depth1 { foo: Some 42 }         : Depth1
{ foo: [42] }  --> Depth2 { foo: Some (Some 42) }   : Depth2
{ foo: null }  --> Depth1 { foo: None }           : Depth1
{ foo: null }  --> Depth2 { foo: None }           : Depth2
{ foo: [] }    --> Depth2 { foo: Some None }       : Depth2

```

Note that the shortcut for records and `Optional` fields does not apply to `Map` (which are also represented as objects), since `Map` relies on absence of key to determine what keys are present in the `Map` to begin with. Nor does it apply to the `[f□, ..., f□]` record form; `Depth1 None` in the array notation must be written as `[null]`.

Type variables may appear in the Daml-LF language, but are always resolved before deciding on a JSON encoding. So, for example, even though `Oa` doesn't appear to contain a nested `Optional`, it may contain a nested `Optional` by virtue of substituting the type variable `a`:

```

record Oa a = { foo: Optional a }

{ foo: 42 }    --> Oa { foo: Some 42 }           : Oa Int
{ }           --> Oa { foo: None }               : Oa Int
{ foo: [] }    --> Oa { foo: Some None }         : Oa (Optional Int)
{ foo: [42] }  --> Oa { foo: Some (Some 42) }    : Oa (Optional Int)

```

In other words, the correct JSON encoding for any LF value is the one you get when you have eliminated all type variables.

Output

Encoded as described above, never applying the shortcut for `None` record fields; e.g. `{ foo: None }` will always encode as `{ foo: null }`.

12.4.2.17 Variant

Variants are expressed as

```
{ tag: constructor, value: argument }
```

For example, if we have

```
variant Foo = Bar Int64 | Baz Unit | Quux (Optional Int64)
```

These are all valid JSON encodings for values of type Foo:

```
{ "tag": "Bar", "value": 42 }
{ "tag": "Baz", "value": {} }
{ "tag": "Quux", "value": null }
{ "tag": "Quux", "value": 42 }
```

Note that Daml data types with named fields are compiled by factoring out the record. So for example if we have

```
data Foo = Bar {f1: Int64, f2: Bool} | Baz
```

We'll get in Daml-LF

```
record Foo.Bar = {f1: Int64, f2: Bool}
variant Foo = Bar Foo.Bar | Baz Unit
```

and then, from JSON

```
{ "tag": "Bar", "value": { "f1": 42, "f2": true } }
{ "tag": "Baz", "value": {} }
```

This can be encoded and used in TypeScript, including exhaustiveness checking; see [a type refinement example](#).

12.4.2.18 Enum

Enums are represented as strings. So if we have

```
enum Foo = Bar | Baz
```

There are exactly two valid JSON values for Foo, `Bar` and `Baz`.

12.4.3 Query Language

The body of `POST /v1/query` looks like so:

```
{
  "templateIds": [...template IDs...],
  "query": {...query elements...}
}
```

The elements of that query are defined here.

12.4.3.1 Fallback Rule

Unless otherwise required by one of the other rules below or to follow, values are interpreted according to [Daml-LF JSON Encoding](#), and compared for equality.

All types are supported by this simple equality comparison except:

- lists
- textmaps
- genmaps

12.4.3.2 Simple Equality

Match records having at least all the (potentially nested) keys expressed in the query. The result record may contain additional properties.

Example: { person: { name: "Bob" }, city: "London" }

Match: { person: { name: "Bob", dob: "1956-06-21" }, city: "London", createdAt: "2019-04-30T12:34:12Z" }

No match: { person: { name: "Bob" }, city: "Zurich" }

Typecheck failure: { person: { name: ["Bob", "Sue"] }, city: "London" }

A JSON object, when considered with a record type, is always interpreted as a field equality query. Its type context is thus mutually exclusive with comparison queries.

12.4.3.3 Comparison Query

Match values on comparison operators for int64, numeric, text, date, and time values. Instead of a value, a key can be an object with one or more operators: { <op>: value } where <op> can be:

- "%lt" for less than
- "%gt" for greater than
- "%lte" for less than or equal to
- "%gte" for greater than or equal to

"%lt" and "%lte" may not be used at the same time, and likewise with "%gt" and "%gte", but all other combinations are allowed.

Example: { "person" { "dob": { "%lt": "2000-01-01", "%gte": "1980-01-01" } } }

Match: { person: { dob: "1986-06-21" } }

No match: { person: { dob: "1976-06-21" } }

No match: { person: { dob: "2006-06-21" } }

These operators cannot occur in objects interpreted in a record context, nor may other keys than these four operators occur where they are legal, so there is no ambiguity with field equality.

12.4.3.4 Appendix: Type-aware Queries

This section is non-normative.

This is not a JSON query language, it is a *Daml-LF* query language. So, while we could theoretically treat queries (where not otherwise interpreted by the `may` contain additional properties rule above) without concern for what LF type (i.e. template) we're considering, we *will not* do so.

Consider the subquery `{"foo": "bar"}`. This query conforms to types, among an unbounded number of others:

```
record A □ { foo : Text }
record B □ { foo : Optional Text }
variant C □ foo : Party | bar : Unit

// NB: LF does not require any particular case for VariantCon or Field;
// these are perfectly legal types in Daml-LF packages
```

In the cases of A and B, "foo" is part of the query language, and only "bar" is treated as an LF value; in the case of C, the whole query is treated as an LF value. The wide variety of ambiguous interpretations about what elements are interpreted, and what elements treated as literal, and how those elements are interpreted or compared, would preclude many techniques for efficient query compilation and LF value representation that we might otherwise consider.

Additionally, it would be extremely easy to overlook unintended meanings of queries when writing them, and impossible in many cases to suppress those unintended meanings within the query language. For example, there is no way that the above query could be written to match A but never C.

For these reasons, as with LF value input via JSON, queries written in JSON are also always interpreted with respect to some specified LF types (e.g. template IDs). For example:

```
{
  "templateIds": ["Foo:A", "Foo:B", "Foo:C"],
  "query": {"foo": "bar"}
}
```

will treat "foo" as a field equality query for A and B, and (supposing templates' associated data types were permitted to be variants, which they are not, but for the sake of argument) as a whole value equality query for C.

The above Typecheck failure happens because there is no LF type to which both "Bob" and ["Bob", "Sue"] conform; this would be caught when interpreting the query, before considering any contracts.

12.4.3.5 Appendix: Known Issues

When Using Oracle, Queries Fail if a Token Is Too Large

This limitation is exclusive to users of the HTTP JSON API using Daml Enterprise support for Oracle. Due to a known limitation in Oracle, the full-test JSON search index on the contract payloads rejects query tokens larger than 256 bytes. This limitations shouldn't impact most workloads, but if this needs to be worked around, the HTTP JSON API server can be started passing the additional `disableContractPayloadIndexing=true` (after wiping an existing query store database, if necessary).

[Issue on GitHub](#)

12.4.4 Use JavaScript Client Libraries with Daml

The JavaScript client libraries allow you to easily build frontend applications that interact with the [HTTP JSON API service](#).

These libraries can dramatically reduce the time necessary to develop a full-stack application by abstracting away implementation details, particularly when building a prototype or an application with relatively simple requirements.

The [@daml/types](#) library contains the TypeScript data types corresponding to primitive Daml data types, such as `Party` or `Text`. Apart from its usefulness for TypeScript developers, the library can also be pulled in as a development-type dependency for JavaScript projects to take advantage of tooling integration with the TypeScript ecosystem, such as the availability of autocompletion on Visual Studio Code.

The [@daml/ledger](#) library contains functions used to interact with the endpoints exposed by HTTP JSON API service and forms the basic layer of functionality. At this layer, you can easily query for active contracts from the ledger, create new ones or exercise choices. This layer is agnostic with regards to any specific framework required to build the frontend.

Finally, if you are a [React.js](#) user, you can take advantage of the [@daml/react](#) library, which builds on top of [@daml/ledger](#) with extensions specific to React.js. This bridges the gap between the basic functionality and the infrastructure required to build a React.js-based frontend application. If you want to start from a ready-made application that uses this library you can start running from the following template:

```
daml new --template create-daml-app <name-of-your-project>
```

To use these libraries, you need to use the [JavaScript Code Generator](#) to automatically generate TypeScript containing metadata about Daml packages.

12.4.4.1 Use the JavaScript Code Generator

The command `daml codegen js` generates JavaScript (and TypeScript) that can be used in conjunction with the [JavaScript Client Libraries](#) for interacting with a Daml ledger via the [HTTP JSON API](#).

Inputs to the command are DAR files. Outputs are JavaScript packages with TypeScript typings containing metadata and types for all Daml packages included in the DAR files.

The generated packages use the library [@daml/types](#).

Generate and Use Code

In outline, the command to generate JavaScript and TypeScript typings from Daml is `daml codegen js -o OUTDIR DAR` where `DAR` is the path to a DAR file (generated via `daml build`) and `OUTDIR` is a directory where you want the artifacts to be written.

Here's a complete example on a project built from the standard `skeleton` template.

```
1 daml new my-proj --template skeleton # Create a new project based off the
  ↪ skeleton template
2 cd my-proj # Enter the newly created project directory
3 daml build # Compile the project's Daml files into a DAR
4 daml codegen js -o daml.js .daml/dist/my-proj-0.0.1.dar # Generate JavaScript
  ↪ packages in the daml.js directory
```

On execution of these commands:

- The directory `my-proj/daml.js` contains generated JavaScript packages with TypeScript typings;
- The files are arranged into directories;
- One of those directories will be named `my-proj-0.0.1` and will contain the definitions corresponding to the Daml files in the project;
- For example, `daml.js/my-proj-0.0.1/lib/index.js` provides access to the definitions for `daml/Main.daml`;
- The remaining directories correspond to modules of the Daml standard library;
- Those directories have numeric names (the names are hashes of the Daml-LF package they are derived from).

To get a quickstart idea of how to use what has been generated, you may wish to jump to the [Templates and choices](#) section and return to the reference material that follows as needed.

Primitive Daml Types: `@daml/types`

To understand the TypeScript typings produced by the code generator, it is helpful to keep in mind this quick review of the TypeScript equivalents of the primitive Daml types provided by `@daml/types`.

Interfaces:

```
Template<T extends object, K = unknown>
Choice<T extends object, C, R, K = unknown>
```

Types:

Daml	TypeScript	TypeScript definition
()	Unit	{}
Bool	Bool	boolean
Int	Int	string
Decimal	Decimal	string
Numeric v	Numeric	string
Text	Text	string
Time	Time	string
Party	Party	string
[τ]	List<τ>	τ[]
Date	Date	string
ContractId τ	ContractId<τ>	string
Optional τ	Optional<τ>	null (null extends τ ? [] [Exclude<τ, null>] : τ)
TextMap τ	TextMap<τ>	{ [key: string]: τ }
(τ□, τ□)	Tuple□<τ□, τ□>	{_1: τ□; _2: τ□}

Note: The types given in the `TypeScript` column are defined in `@daml/types`.

Note: For n -tuples where $n \geq 3$, representation is analogous with the pair case (the last line of the table).

Note: The TypeScript types `Time`, `Decimal`, `Numeric` and `Int` all alias to `string`. These choices relate to the avoidance of precision loss under serialization over the [json-api](#).

Note: The TypeScript definition of type `Optional<τ>` in the above table might look complicated. It accounts for differences in the encoding of optional values when nested versus when they are not (i.e. top-level). For example, `null` and `"foo"` are two possible values of `Optional<Text>` whereas, `[]` and `["foo"]` are two possible values of type `Optional<Optional<Text>>` (`null` is another possible value, `[null]` is **not**).

Daml to TypeScript Mappings

The mappings from Daml to TypeScript are best explained by example.

Records

In Daml, we might model a person like this.

```
1 data Person =
2   Person with
3     name: Text
4     party: Party
5     age: Int
```

Given the above definition, the generated TypeScript code will be as follows.

```
1 type Person = {
2   name: string;
3   party: daml.Party;
4   age: daml.Int;
5 }
```

Variants

This is a Daml type for a language of additive expressions.

```
1 data Expr a =
2   Lit a
3   | Var Text
4   | Add (Expr a, Expr a)
```

In TypeScript, it is represented as a [discriminated union](#).

```
1 type Expr<a> =
2   | { tag: 'Lit'; value: a }
3   | { tag: 'Var'; value: string }
4   | { tag: 'Add'; value: {_1: Expr<a>, _2: Expr<a>} }
```

Sum-of-products

Let's slightly modify the `Expr a` type of the last section into the following.

```
1 data Expr a =
2   Lit a
3   | Var Text
4   | Add {lhs: Expr a, rhs: Expr a}
```

Compared to the earlier definition, the `Add` case is now in terms of a record with fields `lhs` and `rhs`. This renders in TypeScript like so.

```
1 type Expr<a> =
2   | { tag: 'Lit2'; value: a }
3   | { tag: 'Var2'; value: string }
4   | { tag: 'Add'; value: Expr.Add<a> }
5
6 namespace Expr {
7   type Add<a> = {
8     lhs: Expr<a>;
9     rhs: Expr<a>;
10  }
11 }
```

The thing to note is how the definition of the `Add` case has given rise to a record type definition `Expr.Add`.

Enums

Given a Daml enumeration like this,

```
1 data Color = Red | Blue | Yellow
```

the generated TypeScript will consist of a type declaration and the definition of an associated companion object.

```
1 type Color = 'Red' | 'Blue' | 'Yellow'
2
3 const Color = {
4   Red: 'Red',
5   Blue: 'Blue',
6   Yellow: 'Yellow',
7   keys: ['Red', 'Blue', 'Yellow'],
8 } as const;
```

Templates and Choices

Here is a Daml template of a basic ‘IOU’ contract.

```
1 template Iou
2   with
3     issuer: Party
4     owner: Party
5     currency: Text
6     amount: Decimal
7   where
8     signatory issuer
9     choice Transfer: ContractId Iou
10    with
11      newOwner: Party
12    controller owner
13    do
14      create this with owner = newOwner
```

The `daml codegen js` command generates types for each of the choices defined on the template as well as the template itself.

```

1 type Transfer = {
2   newOwner: daml.Party;
3 }
4
5 type Iou = {
6   issuer: daml.Party;
7   owner: daml.Party;
8   currency: string;
9   amount: daml.Numeric;
10 }

```

Each template results in the generation of a companion object. Here, is a schematic of the one generated from the `Iou` template².

```

1 const Iou: daml.Template<Iou, undefined> & {
2   Archive: daml.Choice<Iou, DA_Internal_Template.Archive, {}, undefined>;
3   Transfer: daml.Choice<Iou, Transfer, daml.ContractId<Iou>, undefined>;
4 } = {
5   /* ... */
6 }

```

The exact details of these companion objects are not important - think of them as representing metadata .

What is important is the use of the companion objects when creating contracts and exercising choices using the `@daml/ledger` package. The following code snippet demonstrates their usage.

```

1 import Ledger from '@daml/ledger';
2 import {Iou, Transfer} from /* ... */;
3
4 const ledger = new Ledger(/* ... */);
5
6 // Contract creation; Bank issues Alice a USD $1MM IOU.
7
8 const iouDetails: Iou = {
9   issuer: 'Chase',
10  owner: 'Alice',
11  currency: 'USD',
12  amount: 1000000.0,
13 };
14 const aliceIouCreateEvent = await ledger.create(Iou, iouDetails);
15 const aliceIouContractId = aliceIouCreateEvent.contractId;
16
17 // Choice execution; Alice transfers ownership of the IOU to Bob.
18
19 const transferDetails: Transfer = {
20   newOwner: 'Bob',
21 }
22 const [bobIouContractId, _] = await ledger.exercise(Transfer, aliceIouContractId,
  ↩ transferDetails);

```

Observe on line 14, the first argument to `create` is the `Iou` companion object and on line 22, the first argument to `exercise` is the `Transfer` companion object.

² The `undefined` type parameter captures the fact that `Iou` has no contract key.

12.4.5 JSON API Production Setup

12.4.5.1 Production Setup

The vast majority of prior documentation focused on ease of testing and on setting up the service to run in a dev environment. From a production perspective, given the wide variety of use-cases, there is far less of an established framework for the deployment of an *HTTP JSON API* server. In this document we will make some recommendations for production deployments.

12.4.5.2 Query Store

Note: Daml Open Source only supports PostgreSQL backends for the *HTTP JSON API* server, but Daml Enterprise also supports Oracle backends.

The *HTTP JSON API* server is a JVM application that uses an in-memory backend by default. This in-memory backend setup is inefficient for larger datasets as every query fetches the entire active contract set for all the templates the query references. For production setups we therefore recommend, at a minimum, that one use a database as a query store. This allows for more efficient data caching and improves query performance. Details for enabling a query store are given below.

The query store is a cached search index and is useful in cases where the application needs to query large active contract sets (ACS). The *HTTP JSON API* server can be configured with PostgreSQL/Oracle (Daml Enterprise only) as the query store backend.

The query store is built by saving the state of the ACS up to the current ledger offset. This allows the *HTTP JSON API* to only request the delta on subsequent queries, making it much faster than requesting the entire ACS every time.

Configuring

For example, to enable the PostgreSQL backend you can add the `query-store` config block in your application config file:

```
query-store {
  base-config {
    user = "postgres"
    password = "password"
    driver = "org.postgresql.Driver"
    url = "jdbc:postgresql://localhost:5432/test?&ssl=true"

    // prefix for table names to avoid collisions, empty by default
    table-prefix = "foo"

    // max pool size for the database connection pool
    pool-size = 12
    //specifies the min idle connections for database connection pool.
    min-idle = 4
    //specifies the idle timeout for the database connection pool.
    idle-timeout = 12s
    //specifies the connection timeout for database connection pool.
    connection-timeout = 90s
  }
  // option setting how the schema should be handled.
  // Valid options are start-only, create-only, create-if-needed-and-start and
  ↪create-and-start
  start-mode = "start-only"
}
```

Consult your database vendor's JDBC driver documentation to learn how to specify a JDBC connection URL that suits your needs.

You can also use the `--query-store-jdbc-config` CLI flag (deprecated), as shown below.

```
daml json-api --ledger-host localhost --ledger-port 6865 --http-port 7575 \
--query-store-jdbc-config "driver=org.postgresql.Driver,url=jdbc:postgresql://
↪localhost:5432/test?&ssl=true,user=postgres,password=password,start-mode=start-
↪only"
```

Managing DB permissions with `start-mode`

The `start-mode` is a custom parameter to specify the initialization and usage of the database backing the query store.

Depending on how you prefer to operate it, you can

- run with `start-mode=create-only` with a user that has exclusive table-creating rights that are required for the query store to operate, and then start it once more with `start-mode=start-only` with a user that can use the aforementioned tables, but that cannot apply schema changes
- run with a user that can both create and use the query store tables by passing `start-mode=create-and-start`
- run with a user that can drop, create and use the query store tables by passing `start-mode=create-if-needed-and-start`

When restarting the *HTTP JSON API* server after a schema has already been created, it's safe practice to always use `start-mode=start-only`.

Data Continuity

The query store is a cache. This means that it is perfectly fine to drop it, as the data it contains is a subset of what can safely be recovered from the ledger.

As such, the query store does not provide data continuity guarantees across versions and furthermore doesn't guarantee that a query store initialized with a previous version of the *HTTP JSON API* will work with a newer version. However, the query store keeps track of the schema version under which it was initialized and *HTTP JSON API* service refuses to start if an old schema is detected when it's run with a newer version.

To evolve, the operator of the *HTTP JSON API* query store needs to drop the database used to hold the *HTTP JSON API* query store, create a new one (consult your database vendor's documentation for instructions), and then (depending on the operator's preferred production setup) should proceed to create and start the server using either `start-mode=create-only` & `start-mode=start-only` or only with `start-mode=create-and-start` as described above.

Behavior Under High Load

As stated [in the overview](#), the *HTTP JSON API* service is optimized for rapid application development and ease of developer onboarding. It is not intended to support every high-performance use case. To understand how a high-load application may reach the limits of its design, you need to consider how the query store works.

First, always keep in mind that *the HTTP JSON API service can only do whatever an ordinary ledger API client application could do, including your own*. That's because it is an ordinary client of [Build Integration with the Ledger API](#). So, if your application's queries are a poor match for the way *HTTP JSON API* service's query store works, it's time to consider cutting out the middleman.

Running a Query

Here is what happens every time you run a query with a configured query store:

1. The query store uses the transaction stream from the gRPC API to update its contract table with an up-to-date view of all active contracts that match the template IDs, interface IDs, and user party set in the request. The payload query is not considered at all; every matching contract is added to the table. This will use the active contract service to skip past most of the transaction stream, if the contract table is empty at that set.
2. A database query is run on the contract table, filtering on template ID/interface ID, party set, and the payload.
3. If contention with concurrent requests is detected, the query store will assume it is behind and catch up by returning to #1. This uses an iterative livelocking strategy, where progress is guaranteed and more concurrency is permitted, rather than exclusive locking.
4. Results are returned to the user.

A websocket query does the same, but any contract that didn't exist at the start of the websocket won't receive the above treatment; the live data described for the websocket query stream is always filtered directly from the gRPC API, just as if no query store was configured.

Storage Overview

Without going into too much detail, here's more or less what is stored under step #1 above, for each contract:

1. full contract ID
2. an integer for the template or interface ID
3. for a template ID, the create arguments, as full JSON
4. for an interface ID, the interface view, as full JSON
5. a list of signatories and observers, i.e. parties

Every query store backend indexes on #2, as we have found this index to be universally beneficial. In addition, the Oracle backend has an index on #3 and #4.

With this indexing arrangement, our testing has indicated reasonable performance for well-matched use cases as explained below for contract tables of up to 100000 contracts.

Well-Matched Use Cases

The query store is, generally speaking, best matched to CRUD-like use cases with relatively stable active contract sets. Here are some more specific characteristics likely to be shared by Daml designs that will perform well with the query store.

1. Workflows properly separated into separate templates. The template ID index is the most efficient part of query store filtering. In addition, contract table updates on separate template IDs do not contend (i.e. cause the reset to step #1 above), so changes to the ledger on other parts of the workflow do not affect queries on the template in question.
2. Queries that return <10% of all active contracts for a given contract type ID and party set. This maximizes the value of storing redundant copies in SQL-queryable form at all, namely, that the HTTP JSON API service does not even need to consider already-stored, unmatched contracts.
3. Queries against a slow participant. If the transaction stream from your ledger API participant server is particularly slow, it may be faster to retrieve most contracts from its local database, even if HTTP JSON API service gets no benefit from #2.
4. Templates with low churn, i.e. most active contracts from the previous query are likely to still be active for the next query. If the query store is likelier to have already stored most of the contracts for that template, the update part of the process will be significantly faster and much less likely to contend.

Ill-Matched Use Cases

By contrast, many Daml applications can yield patterns in the ACS and transactions that hurt the performance of applications built on the HTTP JSON API service. Below are some gotchas that might indicate that your application calls for a custom view, perhaps even stored locally in SQL and managed by your application, beyond what HTTP JSON API service's query store can provide.

1. Workflows that use the state field antipattern. This adds a filter on the relatively inefficient payload query that ought to instead be placed on the template ID. In addition, updates to the state field will needlessly contend with updates to contracts with the state you're interested in.
2. Queries that return a large percentage of active contracts against a given contract type ID and party set. If the query store cannot yield any benefit from letting HTTP JSON API service ignore most contracts on each query it will spend more time updating its contract table than it would

have spent simply reading from the gRPC API and filtering directly, so you might as well turn off the query store.

3. Templates with high churn, i.e. the active contracts during the last query are very unlikely to still be active. In such cases HTTP JSON API service may spend so much time updating its contract table that it washes out any performance advantage from being able to SQL query it afterwards.
4. Contracts with highly-overlapping signatories and observers. When signatories and observers do not intersect, their updates never contend; the more this happens, the more likely updates for queries with different party-sets will contend.

12.4.5.3 Security and Privacy

For an *HTTP JSON API* server, all data is maintained by the operator of the deployment. It is the operator's responsibility to ensure that the data abides by the necessary regulations and confidentiality expectations.

We recommend using the tools documented by PostgreSQL to protect data at rest, and using a secure communication channel between the *HTTP JSON API* server and the PostgreSQL server.

The *HTTP JSON API* server provides TLS support to protect data in transit and over untrusted networks. To enable TLS you must specify both the private key for your server and the certificate chain via the below config block that specifies the `cert-chain-file`, `private-key-file`. You can also set a custom root CA certificate that will be used to validate client certificates via the `trust-collection-file` parameter:

```
ledger-api {
  address = "127.0.0.1"
  port = 6400
  tls {
    enabled = "true"
    // the certificate to be used by the server
    cert-chain-file = "cert-chain.crt"
    // private key of the server
    private-key-file = "pvt-key.pem"
    // trust collection, which means that all client certificates will be
    ↪verified using the trusted
    // certificates in this store. if omitted, the JVM default trust store is
    ↪used.
    trust-collection-file = "root-ca.crt"
  }
}
```

Using the cli options (deprecated), you can specify tls options using `daml json-api -pem server.pem -crt server.crt`. Custom root CA certificate can be set via `--cacrt ca.crt`

For more details on secure Daml infrastructure setup please see this [reference implementation](#)

12.4.5.4 Architecture

Components

A production setup of the *HTTP JSON API* involves the following components:

- the *HTTP JSON API* server
- the query store backend database server
- the ledger

The *HTTP JSON API* server exposes an API to interact with the Ledger. It uses JDBC to interact with its underlying query store in order to cache and serve data efficiently.

The *HTTP JSON API* server releases are regularly tested with the tools described under [System Requirements](#).

In production, we recommend running on a x86_64 architecture in a Linux environment. This environment should have a Java SE Runtime Environment with minimum version as mentioned at [System Requirements](#). We recommend using PostgreSQL server as query-store, again with minimum version as mentioned at [System Requirements](#).

12.4.5.5 Scaling and Redundancy

Note: This section of the document only talks about scaling and redundancy setup for the *HTTP JSON API* server. In all recommendations suggested below we assume that the JSON API is always interacting with a single participant on the ledger.

We recommend dedicating computation and memory resources to the *HTTP JSON API* server and query store components. This can be achieved via containerization or by setting these components up on independent physical servers. Make sure that the two components are **physically co-located** to reduce network latency for communication. Scaling and availability heavily rely on the interactions between the core components listed above.

The general principles of scaling apply here: Try to understand the bottlenecks and see if adding additional processing power/memory helps.

Scaling creates and exercises

The *HTTP JSON API* service provides simple, synchronous endpoints for carrying out creates and exercises on the ledger. It does not support the complex multi-command asynchronous submission protocols supported by the ledger API.

For performing large numbers of creates and exercises at once, while you can perform many HTTP requests at once to carry out this task, it may be simpler and more concurrent-safe to shift more of this logic into a Daml choice that can be exercised.

The pattern looks like this:

1. Have a contract with a key and one or more choices on the ledger.
2. Such a choice can carry out as many creates and exercises as desired; all of these will take place in a single transaction.
3. Use the *HTTP JSON API* service to exercise this choice by key.

It's possible to go too far in the other direction: any error will usually cause the whole transaction to roll back, so an excessively large amount of work done by a single choice can also cause needless retrying. You can solve this by batching requests, or using [Exception Handling](#) to collect and return failed cases to the HTTP JSON API service client for retrying, allowing successful parts of the batch to proceed.

Scaling Queries

The [Query Store](#) is a key factor of efficient queries. However, it behaves very differently depending on the characteristics of the underlying ledger, Daml application, and client query patterns. [Understanding how it works](#) is a major prerequisite to understanding how the HTTP JSON API service will interact with your application's performance profile.

Additionally, the *HTTP JSON API* can be scaled independently of its query store. You can have any number of *HTTP JSON API* instances talking to the same query store (if, for example, your monitoring indicates that the *HTTP JSON API* processing time is the bottleneck), or have each *HTTP JSON API* instance talk to its own independent query store (if the database response times are the bottleneck).

In the latter case, the Daml privacy model ensures that the *HTTP JSON API* requests are made using the user-provided token, thus the data stored in a given query store will be specific to the set of parties that have made queries through that specific query store instance (for a given template). Therefore, if you do run with separate query stores, it may be useful to route queries (using a reverse proxy server) based on requesting party (and possibly queried template), which would minimize the amount of data in each query store as well as the overall redundancy of said data.

Users may consider running PostgreSQL backend in a [high availability configuration](#). The benefits of this are use-case dependent as this may be more expensive for smaller active contract datasets, where re-initializing the cache is cheap and fast.

Finally, we recommend using orchestration systems or load balancers which monitor the health of the service and perform subsequent operations to ensure availability. These systems can use the [healthcheck endpoints](#) provided by the *HTTP JSON API* server. This can also be tied into supporting an arbitrary autoscaling implementation in order to ensure a minimum number of *HTTP JSON API* servers on failures.

Hitting a Scaling Bottleneck

As *HTTP JSON API* service and its query store are optimized for rapid application development and ease of developer onboarding, you may reach a point where your application's performance demands exceed what the *HTTP JSON API* service can offer. The more demanding your application is, the less likely it is to be well-matched with the simplifications and generalizations that the *HTTP JSON API* service makes for developer simplicity.

In this case, it's important to remember that *the HTTP JSON API service can only do whatever an ordinary ledger API client application could do, including your own.*

For example, for a JVM application, interacting with JSON is probably simpler than gRPC directly, but using [Java Bindings codegen](#) are much simpler than either.

There is no way to make [Query Store](#) more suited to high-performance queries for your Daml application than a custom data store implemented as your own server on gRPC would be. So an application that must interact over JSON, but requires very high-performance or very high-load query throughput, would usually be better served by a custom server.

Set Up the HTTP JSON API Service To Work With Highly Available Participants

If the participant node itself is configured to be highly available, depending on the setup you may want to choose different approaches to connect to the passive participant node(s). In most setups, including those based on Canton, you'll likely have an active participant node whose role can be taken over by a passive node in case the currently active one drops. Just as for the *HTTP JSON API* itself, you can use orchestration systems or load balancers to monitor the status of the participant nodes and have those point your (possibly highly-available) *HTTP JSON API* nodes to the active participant node.

To learn how to run and monitor Canton with high availability, refer to the [Canton documentation](#).

12.4.5.6 Logging

The *HTTP JSON API* server uses the industry-standard logback for logging. You can read more about it in the [Logback documentation](#).

The logging infrastructure leverages structured logging as implemented by the [Logstash Logback Encoder](#).

Logged events should carry information about the request being served by the *HTTP JSON API* server. This includes the details of the commands being submitted, the endpoints being hit, and the response received – highlighting details of failures if any. When using a traditional logging target (e.g. standard output or rotating files) this information will be part of the log description. Using a logging target compatible with the Logstash Logback Encoder allows one to have rich logs that come with structured information about the event being logged.

The default log encoder used is the plaintext one for traditional logging targets.

12.4.5.7 Metrics

Enable and Configure Reporting

To enable metrics and configure reporting, you can use the below config block in application config:

```
metrics {
  // Start a metrics reporter. Must be one of "console", "csv:///PATH",
  ↪ "graphite://HOST[:PORT][/METRIC_PREFIX]", or "prometheus://HOST[:PORT]".
  reporter = "prometheus://localhost:9000"
  // Set metric reporting interval , examples : 1s, 30s, 1m, 1h
  reporting-interval = 30s
}
```

or the two following CLI options (deprecated):

- `--metrics-reporter`: passing a legal value will enable reporting; the accepted values are as follows:
 - `console`: prints captured metrics on the standard output
 - `csv://</path/to/metrics.csv>`: saves the captured metrics in CSV format at the specified location
 - `graphite://<server_host>[:<server_port>]`: sends captured metrics to a Graphite server. If the port is omitted, the default value 2003 will be used.

- `prometheus://<server_host>[:<server_port>]`: renders captured metrics on a http endpoint in accordance with the prometheus protocol. If the port is omitted, the default value 55001 will be used. The metrics will be available under the address `http://<server_host>:<server_port>/metrics`.
- `--metrics-reporting-interval`: allows the user to set the interval at which metrics are pre-aggregated on the *HTTP JSON API* and sent to the reporter. The formats accepted are based on the ISO 8601 duration format `PnDTnHnMn.nS` with days considered to be exactly 24 hours. The default interval is 10 seconds.

Types of Metrics

This is a list of type of metrics with all data points recorded for each. Use this as a reference when reading the list of metrics.

Counter

Number of occurrences of some event.

Meter

A meter tracks the number of times a given event occurred (throughput). The following data points are kept and reported by any meter.

```
<metric.qualified.name>.count: number of registered data points overall
<metric.qualified.name>.m1_rate: number of registered data points per minute
<metric.qualified.name>.m5_rate: number of registered data points every 5 minutes
<metric.qualified.name>.m15_rate: number of registered data points every 15 minutes
<metric.qualified.name>.mean_rate: mean number of registered data points
```

Timers

A timer records the time necessary to execute a given operation (in fractional milliseconds).

Metrics Reference

The HTTP JSON API Service supports [common HTTP metrics](#). In addition, see the following list of important metrics:

`daml.http_json_api.incoming_json_parsing_and_validation_timing`

A timer. Measures latency (in milliseconds) for parsing and decoding of an incoming json payload

`daml.http_json_api.response_creation_timing`

A timer. Measures latency (in milliseconds) for construction of the response json payload.

`daml.http_json_api.db_find_by_contract_key_timing`

A timer. Measures latency (in milliseconds) of the find by contract key database operation.

`daml.http_json_api.db_find_by_contract_id_timing`

A timer. Measures latency (in milliseconds) of the find by contract id database operation.

`daml.http_json_api.command_submission_ledger_timing`

A timer. Measures latency (in milliseconds) for processing the command submission requests on the ledger.

`daml.http_json_api.websocket_request_count`

A Counter. Counts active websocket connections.

12.5 Build Integration with the Ledger API

To write an application around a Daml ledger, you will need to interact with the **Ledger API**.

Every ledger that Daml can run on exposes this same API.

12.5.1 What's in the Ledger API

The Ledger API exposes the following services:

Submitting commands to the ledger

- Use the [command submission service](#) to submit commands (create a contract or exercise a choice) to the ledger.
- Use the [command completion service](#) to track the status of submitted commands.
- Use the [command service](#) for a convenient service that combines the command submission and completion services.

Reading from the ledger

- Use the [transaction service](#) to stream committed transactions and the resulting events (choices exercised, and contracts created or archived), and to look up transactions.

- Use the [active contracts service](#) to quickly bootstrap an application with the currently active contracts. It saves you the work to process the ledger from the beginning to obtain its current state.

Utility services

- Use the [party management service](#) to allocate and find information about parties on the Daml ledger.
- Use the [package service](#) to query the Daml packages deployed to the ledger.
- Use the [ledger identity service](#) to retrieve the Ledger ID of the ledger the application is connected to.
- Use the [ledger configuration service](#) to retrieve some dynamic properties of the ledger, like maximum deduplication duration for commands.
- Use the [version service](#) to retrieve information about the Ledger API version.
- Use the [user management service](#) to manage users and their rights.
- Use the [metering report service](#) to retrieve a participant metering report.

Testing services (on Sandbox only, not for production ledgers)

- Use the [time service](#) to obtain the time as known by the ledger.

For full information on the services see [The Ledger API Services](#).

You may also want to read the [protobuf documentation](#), which explains how each service is defined as protobuf messages.

12.5.2 How to Access the Ledger API

You can access the Ledger API via the [Java Bindings](#) or the [Python Bindings](#) (formerly known as DAZL).

If you don't use a language that targets the JVM or Python, you can use gRPC to generate the code to access the Ledger API in several supported programming languages. [Further documentation](#) provides a few pointers on how you may want to approach this.

You can also use the [HTTP JSON API Service](#) to tap into the Ledger API.

At its core, this service provides a simplified view of the active contract set and additional primitives to query it and exposing it using a well-defined JSON-based encoding over a conventional HTTP connection.

A subset of the services mentioned above is also available as part of the HTTP JSON API.

12.5.3 Daml-LF

When you [compile Daml source into a .dar file](#), the underlying format is Daml-LF. Daml-LF is similar to Daml, but is stripped down to a core set of features. The relationship between the surface Daml syntax and Daml-LF is loosely similar to that between Java and JVM bytecode.

As a user, you don't need to interact with Daml-LF directly. But internally, it's used for:

- Executing Daml code on the Sandbox or on another platform
- Sending and receiving values via the Ledger API (using a protocol such as gRPC)
- Generating code in other languages for interacting with Daml models (often called `codegen`)

12.5.3.1 When You Need to Know About Daml-LF

Daml-LF is only really relevant when you're dealing with the objects you send to or receive from the ledger. If you use any of the provided language bindings for the Ledger API, you don't need to know about Daml-LF at all, because this generates idiomatic representations of Daml for you.

Otherwise, it can be helpful to know what the types in your Daml code look like at the Daml-LF level, so you know what to expect from the Ledger API.

For example, if you are writing an application that creates some Daml contracts, you need to construct values to pass as parameters to the contract. These values are determined by the Daml-LF types in that contract template. This means you need an idea of how the Daml-LF types correspond to the types in the original Daml model.

For the most part the translation of types from Daml to Daml-LF should not be surprising. [This page goes through all the cases in detail](#).

For the bindings to your specific programming language, you should refer to the language-specific documentation.

12.5.4 The Ledger API Services

The Ledger API is structured as a set of services. The core services are implemented using [gRPC](#) and [Protobuf](#), but most applications access this API through the mediation of the language bindings.

This page gives more detail about each of the services in the API, and will be relevant whichever way you're accessing it.

If you want to read low-level detail about each service, see the [protobuf documentation of the API](#).

12.5.4.1 Overview

The API is structured as two separate data streams:

- A stream of **commands** TO the ledger that allow an application to submit transactions and change state.

- A stream of **transactions** and corresponding **events** FROM the ledger that indicate all state changes that have taken place on the ledger.

Commands are the only way an application can cause the state of the ledger to change, and events are the only mechanism to read those changes.

For an application, the most important consequence of these architectural decisions and implementation is that the Ledger API is asynchronous. This means:

- The outcome of commands is only known some time after they are submitted.

- The application must deal with successful and erroneous command completions separately from command submission.

- Ledger state changes are indicated by events received asynchronously from the command submissions that cause them.

The need to handle these issues is a major determinant of application architecture. Understanding the consequences of the API characteristics is important for a successful application design.

For more help understanding these issues so you can build correct, performant and maintainable applications, read the [application architecture guide](#).

Glossary

The ledger is a list of transactions. The transaction service returns these.

A transaction is a tree of actions, also called events, which are of type `create`, `exercise` or `archive`. The transaction service can return the whole tree, or a flattened list.

A submission is a proposed transaction, consisting of a list of commands, which correspond to the top-level actions in that transaction.

A completion indicates the success or failure of a submission.

12.5.4.2 Submit Commands to the Ledger

Command Submission Service

Use the **command submission service** to submit commands to the ledger. Commands either create a new contract, or exercise a choice on an existing contract.

A call to the command submission service will return as soon as the ledger server has parsed the command, and has either accepted or rejected it. This does not mean the command has been executed, only that the server has looked at the command and decided that its format is acceptable, or has rejected it for syntactic or content reasons.

The on-ledger effect of the command execution will be reported via the [transaction service](#), described below. The completion status of the command is reported via the [command completion service](#). Your application should receive completions, correlate them with command submission, and handle errors and failed commands. Alternatively, you can use the [command service](#), which conveniently wraps the command submission and completion services.

Change ID

Each intended ledger change is identified by its **change ID**, consisting of the following three components:

- The submitting parties, i.e., the union of [party](#) and [act_as](#)
- the [application ID](#)
- The [command ID](#)

Application-specific IDs

The following application-specific IDs, all of which are included in completion events, can be set in commands:

- A [submission ID](#), returned to the submitting application only. It may be used to correlate specific submissions to specific completions.

- A [command ID](#), returned to the submitting application only; it can be used to correlate commands to completions.

- A [workflow ID](#), returned as part of the resulting transaction to all applications receiving it. It can be used to track workflows between parties, consisting of several transactions.

For full details, see [the proto documentation for the service](#).

Command Deduplication

The command submission service deduplicates submitted commands based on their [change ID](#).

Applications can provide a deduplication period for each command. If this parameter is not set, the default maximum deduplication duration is used.

A command submission is considered a duplicate submission if the Ledger API server is aware of another command within the deduplication period and with the same [change ID](#).

A command resubmission will generate a rejection until the original submission was rejected (i.e. the command failed and resulted in a rejected transaction) or until the effective deduplication period has elapsed since the completion of the original command, whichever comes first.

Command deduplication is only *guaranteed* to work if all commands are submitted to the same participant. Ledgers are free to perform additional command deduplication across participants. Consult the respective ledger's manual for more details.

For details on how to use command deduplication, see the [Command Deduplication Guide](#).

Explicit contract disclosure (experimental)

Starting with Canton 2.7, Ledger API clients can use explicit contract disclosure to submit commands with attached disclosed contracts received from third parties. For more details, see [Explicit contract disclosure](#).

Command Completion Service

Use the **command completion service** to find out the completion status of commands you have submitted.

Completions contain the [command ID](#) of the completed command, and the completion status of the command. This status indicates failure or success, and your application should use it to update what it knows about commands in flight, and implement any application-specific error recovery.

For full details, see [the proto documentation for the service](#).

Command Service

Use the **command service** when you want to submit a command and wait for it to be executed. This service is similar to the command submission service, but also receives completions and waits until it knows whether or not the submitted command has completed. It returns the completion status of the command execution.

You can use either the command or command submission services to submit commands to effect a ledger change. The command service is useful for simple applications, as it handles a basic form of coordination between command submission and completion, correlating submissions with completions, and returning a success or failure status. This allows simple applications to be completely stateless, and alleviates the need for them to track command submissions.

For full details, see [the proto documentation for the service](#).

12.5.4.3 Read From the Ledger

Transaction Service

Use the **transaction service** to listen to changes in the ledger state, reported via a stream of transactions.

Transactions detail the changes on the ledger, and contains all the events (create, exercise, archive of contracts) that had an effect in that transaction.

Transactions contain a [transaction ID](#) (assigned by the server), the [workflow ID](#), the [command ID](#), and the events in the transaction.

Subscribe to the transaction service to read events from an arbitrary point on the ledger. This arbitrary point is specified by the ledger offset. This is important when starting or restarting and application, and to work in conjunction with the [active contracts service](#).

For full details, see [the proto documentation for the service](#).

Transaction and transaction Trees

TransactionService offers several different subscriptions. The most commonly used is GetTransactions. If you need more details, you can use GetTransactionTrees instead, which returns transactions as flattened trees, represented as a map of event IDs to events and a list of root event IDs.

Verbosity

The service works in a non-verbose mode by default, which means that some identifiers are omitted:

- Record IDs
- Record field labels
- Variant IDs

You can get these included in requests related to Transactions by setting the `verbose` field in message `GetTransactionsRequest` or `GetActiveContractsRequest` to `true`.

Transaction Filter

TransactionService offers transaction subscriptions filtered by templates and interfaces using `GetTransactions` calls. A [transaction filter](#) in `GetTransactionsRequest` allows:

- filtering by a party, when the [inclusive](#) field is left empty
- filtering by a party and [template ID](#)
- filtering by a party and [interface ID](#)
- exposing an interface view, when the [include_interface_view](#) is set to `true`
- exposing a created event blob to be used for a disclosed contract in command submission when `include_created_event_blob` is set to `true` in either [TemplateFilter](#) or [InterfaceFilter](#)

Note: The [template_ids](#) field is deprecated as of Canton 2.8.0 and will be removed in future releases. Use [template_filter](#) instead.

Active Contracts Service

Use the **active contracts service** to obtain a party-specific view of all contracts that are active on the ledger at the time of the request.

The active contracts service returns its response as a stream of batches of the created events that would re-create the state being reported (the size of these batches is left to the ledger implementation). As part of the last message, the offset at which the reported active contract set was valid is included. This offset can be used to subscribe to the `flat transactions` stream to keep a consistent view of the active contract set without querying the active contract service further.

This is most important at application start, if the application needs to synchronize its initial state with a known view of the ledger. Without this service, the only way to do this would be to read the Transaction Stream from the beginning of the ledger, which can be prohibitively expensive with a large ledger.

For full details, see [the proto documentation for the service](#).

Verbosity

See [Verbosity](#) above.

Transaction Filter

See [Transaction Filter](#) above.

Note: The RPCs exposed as part of the transaction and active contracts services make use of offsets.

An offset is an opaque string of bytes assigned by the participant to each transaction as they are received from the ledger. Two offsets returned by the same participant are guaranteed to be lexicographically ordered: while interacting with a single participant, the offset of two transactions can be compared to tell which was committed earlier. The state of a ledger (i.e. the set of active contracts) as exposed by the Ledger API is valid at a specific offset, which is why the last message your application receives when calling the `ActiveContractsService` is precisely that offset. In this way, the client can keep track of the relevant state without needing to invoke the `ActiveContractsService` again, by starting to read transactions from the given offset.

Offsets are also useful to perform crash recovery and failover as documented more in depth in the [application architecture](#) page.

You can read more about offsets in the [protobuf documentation of the API](#).

Event Query Service

Use the **event query service** to obtain a party-specific view of contract events.

The gRPC API provides ledger streams to off-ledger components that maintain a queryable state. This service allows you to make simple event queries without off-ledger components like the JSON API.

Using the Event Query Service, you can create, retrieve, and archive events associated with a contract ID or contract key. The API returns only those events where at least one of the requesting parties is a stakeholder of the contract. If the contract is still active, the `archive_event` is unset.

Contract keys can be used by multiple contracts over time. The latest contract events are returned first. To access earlier contract key events, use the `continuation_token` returned in the `GetEventsByContractKeyResponse` in a subsequent `GetEventsByContractKeyRequest`.

If no events match the request criteria or the requested events are not visible to the requesting parties, an empty structure is returned. Events associated with consumed contracts are returned until they are pruned.

Note: When querying by contract key, the key value must be structured in the same way as the key returned in the create event.

For full details, see [the proto documentation for the service](#).

12.5.4.4 Utility Services

Party Management Service

Use the **party management service** to allocate parties on the ledger, update party properties local to the participant and retrieve information about allocated parties.

Parties govern on-ledger access control as per [Daml's privacy model](#) and [authorization rules](#). Applications and their operators are expected to allocate and use parties to manage on-ledger access control as per their business requirements.

For more information, refer to the pages on [Identity Management](#) and [the API reference documentation](#).

User Management Service

Use the **user management service** to manage the set of users on a participant node and their [access rights](#) to that node's Ledger API services and as the integration point for your organization's IAM (Identity and Access Management) framework.

Daml 2.0 introduced the concept of the user in Daml. While a party represents a single individual with a single set of rights and is universal across participant nodes, a user is local to a specific participant node. Each user is typically associated with a primary party and is given the right to act as or read as other parties. Every participant node will maintain its own mapping from its user ids to the parties that they can act and/or read as. Also, when used, the user's ids will serve as application ids. Thus, participant users can be used to manage the permissions of Daml applications (i.e. to authorize applications to read as or act as certain parties). Unlike a JWT token-based system, the user management system does not limit the number of parties that the user can act or read as.

The relation between a participant node's users and Daml parties is best understood by analogy to classical databases: a participant node's users are analogous to database users while Daml parties are analogous to database roles. Further, the rights granted to a user are analogous to the user's assigned database roles.

For more information, consult the [the API reference documentation](#) for how to list, create, update, and delete users and their rights. See the [UserManagementFeature descriptor](#) to learn about the limits of the user management service, e.g., the maximum number of rights per user. The feature descriptor can be retrieved using the [Version service](#).

With user management enabled you can use both new user-based and old custom Daml authorization tokens. Consult the [Authorization documentation](#) to understand how Ledger API requests are authorized, and how to use user management to dynamically change an application's rights.

User management is available in Canton-enabled drivers and not yet available in the Daml for VMware Blockchain driver.

Identity Provider Config Service

Use **identity provider config service** to define and manage the parameters of an external IDP systems configured to issue tokens for a participant node.

The **identity provider config service** makes it possible for participant node administrators to set up and manage additional identity providers at runtime. This allows using access tokens from identity providers unknown at deployment time. When an identity provider is configured, independent IDP administrators can manage their own set of parties and users.

Such parties and users have a matching `identity_provider_id` defined and are inaccessible to administrators from other identity providers. A user will only be authenticated if the corresponding JWT token is issued by the appropriate identity provider. Users and parties without `identity_provider_id` defined are assumed to be using the default identity provider, which is configured statically when the participant node is deployed.

For full details, see [the proto documentation for the service](#).

Package Service

Use the **package service** to obtain information about Daml packages available on the ledger.

This is useful for obtaining type and metadata information that allow you to interpret event data in a more useful way.

For full details, see [the proto documentation for the service](#).

Ledger Identity Service (DEPRECATED)

Use the **ledger identity service** to get the identity string of the ledger that your application is connected to.

Including identity string is optional for all Ledger API requests. If you include it, commands with an incorrect identity string will be rejected.

For full details, see [the proto documentation for the service](#).

Ledger Configuration Service

Use the **ledger configuration service** to subscribe to changes in ledger configuration.

This configuration includes the maximum command deduplication period (see [Command Deduplication](#) for details).

For full details, see [the proto documentation for the service](#).

Version Service

Use the **version service** to retrieve information about the Ledger API version and what optional features are supported by the ledger server.

For full details, see [the proto documentation for the service](#).

Pruning Service

Use the **pruning service** to prune archived contracts and transactions before or at a given offset.

For full details, see [the proto documentation for the service](#).

Metering Report Service

Use the **metering report service** to retrieve a participant metering report.

For full details, see [the proto documentation for the service](#).

12.5.4.5 Testing Services

These are only for use for testing with the Sandbox, not for on production ledgers.

Time Service

Use the **time service** to obtain the time as known by the ledger server.

For full details, see [the proto documentation for the service](#).

12.5.5 Java Bindings

The Java bindings is a client implementation of the *Ledger API* based on [RxJava](#), a library for composing asynchronous and event-based programs using observable sequences for the Java VM. It provides an idiomatic way to write Daml Ledger applications.

See also:

This documentation for the Java bindings API includes the [JavaDoc reference documentation](#).

12.5.5.1 Overview

The Java bindings library is composed of:

The Data Layer A Java-idiomatic layer based on the Ledger API generated classes. This layer simplifies the code required to work with the Ledger API.

Can be found in the java package `com.daml.ledger.javaapi.data`.

The Reactive Layer A thin layer built on top of the Ledger API services generated classes.

For each Ledger API service, there is a reactive counterpart with a matching name. For instance, the reactive counterpart of `ActiveContractsServiceGrpc` is `ActiveContractsClient`.

The Reactive Layer also exposes the main interface representing a client connecting via the Ledger API. This interface is called `LedgerClient` and the main implementation working against a Daml Ledger is the `DamlLedgerClient`.

Can be found in the java package `com.daml.ledger.rxjava`.

Generate Code

When writing applications for the ledger in Java, you want to work with a representation of Daml templates and data types in Java that closely resemble the original Daml code while still being as true to the native types in Java as possible.

To achieve this, you can use Daml to Java code generator (`Java codegen`) to generate Java types based on a Daml model. You can then use these types in your Java code when reading information from and sending data to the ledger.

For more information on Java code generation, see [Generate Java Code from Daml](#).

Connect to the Ledger: `LedgerClient`

Connections to the ledger are made by creating instance of classes that implement the interface `LedgerClient`. The class `DamlLedgerClient` implements this interface, and is used to connect to a Daml ledger.

This class provides access to the `ledgerId`, and all clients that give access to the various ledger services, such as the active contract set, the transaction service, the time service, etc. This is described [below](#). Consult the [JavaDoc for `DamlLedgerClient`](#) for full details.

12.5.5.2 Reference Documentation

[Click here for the JavaDoc reference documentation.](#)

12.5.5.3 Get Started

The Java bindings library can be added to a [Maven](#) project.

Set Up a Maven Project

To use the Java bindings library, add the following dependencies to your project's `pom.xml`:

```
<dependencies>
  <dependency>
    <groupId>com.daml</groupId>
    <artifactId>bindings-rxjava</artifactId>
    <version>x.y.z</version>
  </dependency>
</dependencies>
```

Replace `x.y.z` for both dependencies with the version that you want to use. You can find the available versions by checking the [Maven Central Repository](#).

You can also take a look at the `pom.xml` file from the [quickstart project](#).

Connect to the Ledger

Before any ledger services can be accessed, you must establish a connection to the ledger by creating an instance of a `DamlLedgerClient`. To create an instance of a ledger client, use the static `newBuilder(..)` method to create a `DamlLedgerClient.Builder`. Then use the builder instance to create the `DamlLedgerClient`. Finally, call the `connect()` method on the client.

```
// Create a client object to access services on the ledger.
DamlLedgerClient client = DamlLedgerClient.newBuilder(ledgerhost, ledgerport).
    ↪build();

// Connects to the ledger and runs initial validation.
client.connect();
```

Perform Authorization

Some ledgers will require you to send an access token along with each request.

To learn more about authorization, read the [Authorization](#) overview.

To use the same token for all Ledger API requests, the `DamlLedgerClient` builders expose a `withAccessToken` method. This will allow you to not pass a token explicitly for every call.

If your application is long-lived and your tokens are bound to expire, you can reload the necessary token when needed and pass it explicitly for every call. Every client method has an overload that allows a token to be passed, as in the following example:

```
transactionClient.getLedgerEnd(); // Uses the token specified when constructing
↳ the client
transactionClient.getLedgerEnd(accessToken); // Override the token for this call
↳ exclusively
```

If you're communicating with a ledger that verifies authorization it's very important to secure the communication channel to prevent your tokens to be exposed to man-in-the-middle attacks. The next chapter describes how to enable TLS.

Connect Securely

The Java bindings library lets you connect to a Daml Ledger via a secure connection. The builders created by `DamlLedgerClient.newBuilder` default to a plaintext connection, but you can invoke `withSslContext` to pass an `SslContext`. Using the default plaintext connection is useful only when connecting to a locally running Sandbox for development purposes.

Secure connections to a Daml Ledger must be configured to use client authentication certificates, which can be provided by a Ledger Operator.

For information on how to set up an `SslContext` with the provided certificates for client authentication, please consult the gRPC documentation on [TLS with OpenSSL](#) as well as the [HelloWorldClientTls](#) example of the `grpc-java` project.

Advanced Connection Settings

Sometimes the default settings for gRPC connections/channels are not suitable for a given situation. These use cases are supported by creating a custom `NettyChannelBuilder` object and passing the it to the `newBuilder` static method defined over `DamlLedgerClient`.

12.5.5.4 Example Projects

Example projects using the Java bindings are available on [GitHub](#). [Read more about them here](#).

12.5.5.5 Generate Java Code from Daml

Introduction

When writing applications for the ledger in Java, you want to work with a representation of Daml templates and data types in Java that closely resemble the original Daml code while still being as true to the native types in Java as possible. To achieve this, you can use Daml to Java code generator (`Java codegen`) to generate Java types based on a Daml model. You can then use these types in your Java code when reading information from and sending data to the ledger.

The [Daml assistant documentation](#) describes how to run and configure the code generator for all supported bindings, including Java.

The rest of this page describes Java-specific topics.

Understand the Generated Java Model

The Java codegen generates source files in a directory tree under the output directory specified on the command line.

Map Daml Primitives to Java Types

Daml built-in types are translated to the following equivalent types in Java:

Daml type	Java type	Java Bindings Value Type
Int	<code>java.lang.Long</code>	Int64
Numeric	<code>java.math.BigDecimal</code>	Numeric
Text	<code>java.lang.String</code>	Text
Bool	<code>java.util.Boolean</code>	Bool
Party	<code>java.lang.String</code>	Party
Date	<code>java.time.LocalDate</code>	Date
Time	<code>java.time.Instant</code>	Timestamp
List or []	<code>java.util.List</code>	DamlList
TextMap	<code>java.util.Map</code> Restricted to using String keys.	Daml-TextMap
Optional	<code>java.util.Optional</code>	DamlOptional
() (Unit)	None since the Java language doesn't have a direct equivalent of Daml's Unit type (), the generated code uses the Java Bindings value type.	Unit
ContractId	Fields of type <code>ContractId X</code> refer to the generated <code>ContractId</code> class of the respective template X.	ContractId

Understand Escaping Rules

To avoid clashes with Java keywords, the Java codegen applies escaping rules to the following Daml identifiers:

- Type names (except the already mapped *built-in types*)
- Constructor names
- Type parameters
- Module names
- Field names

If any of these identifiers match one of the [Java reserved keywords](#), the Java codegen appends a dollar sign \$ to the name. For example, a field with the name `import` will be generated as a Java field with the name `import$`.

Understand the Generated Classes

Every user-defined data type in Daml (template, record, and variant) is represented by one or more Java classes as described in this section.

The Java package for the generated classes is the equivalent of the lowercase Daml module name.

Listing 1: Daml

```
module Foo.Bar.Baz where
```

Listing 2: Java

```
package foo.bar.baz;
```

Records (a.k.a Product Types)

A [Daml record](#) is represented by a Java class with fields that have the same name as the Daml record fields. A Daml field having the type of another record is represented as a field having the type of the generated class for that record.

Listing 3: Com/Acme/ProductTypes.daml

```
module Com.Acme.ProductTypes where

data Person = Person with name : Name; age : Decimal
data Name = Name with firstName : Text; lastName : Text
```

A Java file is generated that defines the class for the type `Person`:

Listing 4: com/acme/producttypes/Person.java

```
package com.acme.producttypes;

public class Person extends DamlRecord<Person> {
    public final Name name;
    public final BigDecimal age;
```

(continues on next page)

(continued from previous page)

```

public static Person fromValue(Value value$) { /* ... */ }

public Person(Name name, BigDecimal age) { /* ... */ }
public DamlRecord toValue() { /* ... */ }
}

```

A Java file is generated that defines the class for the type Name:

Listing 5: com/acme/producttypes/Name.java

```

package com.acme.producttypes;

public class Name extends DamlRecord<Name> {
    public final String firstName;
    public final String lastName;

    public static Person fromValue(Value value$) { /* ... */ }

    public Name(String firstName, String lastName) { /* ... */ }
    public DamlRecord toValue() { /* ... */ }
}

```

Templates

The Java codegen generates three classes for a Daml template:

TemplateName Represents the contract data or the template fields.

TemplateName.ContractId Used whenever a contract ID of the corresponding template is used in another template or record, for example: data Foo = Foo (ContractId Bar). This class also provides methods to generate an `ExerciseCommand` for each choice that can be sent to the ledger with the Java Bindings.

TemplateName.Contract Represents an actual contract on the ledger. It contains a field for the contract ID (of type `TemplateName.ContractId`) and a field for the template data (of type `TemplateName`). With the static method `TemplateName.Contract.fromCreatedEvent`, you can deserialize a [CreatedEvent](#) to an instance of `TemplateName.Contract`.

Listing 6: Com/Acme/Templates.daml

```

module Com.Acme.Templates where

data BarKey =
    BarKey
    with
        p : Party
        t : Text

template Bar
    with
        owner: Party
        name: Text
    where

```

(continues on next page)

(continued from previous page)

```

signatory owner

key BarKey owner name : BarKey
maintainer key.p

choice Bar_SomeChoice: Bool
  with
    aName: Text
    controller owner
  do return True

```

A file is generated that defines five Java classes and an interface:

1. Bar
2. Bar.ContractId
3. Bar.Contract
4. Bar.CreateAnd
5. Bar.ByKey
6. Bar.Exercises

Listing 7: com/acme/templates/Bar.java

```

package com.acme.templates;

public class Bar extends Template {

    public static final Identifier TEMPLATE_ID = new Identifier("some-package-id",
↳ "Com.Acme.Templates", "Bar");

    public static final Choice<Bar, Archive, Unit> CHOICE_Archive =
        Choice.create(/* ... */);

    public static final ContractCompanion.WithKey<Contract, ContractId, Bar, BarKey>
↳ COMPANION =
        new ContractCompanion.WithKey<>("com.acme.templates.Bar",
            TEMPLATE_ID, ContractId::new, Bar::fromValue, Contract::new, e -> BarKey.
↳ fromValue(e), List.of(CHOICE_Archive));

    public final String owner;
    public final String name;

    public CreateAnd createAnd() { /* ... */ }

    public static ByKey byKey(BarKey key) { /* ... */ }

    public static class ContractId extends com.daml.ledger.javaapi.data.codegen.
↳ ContractId<Bar>
        implements Exercises<ExerciseCommand> {
        // inherited:
        public final String contractId;
    }

    public interface Exercises<Cmd> extends com.daml.ledger.javaapi.data.codegen.
↳ Exercises<Cmd> {
        default Cmd exerciseArchive(Unit arg) { /* ... */ }
    }

```

(continues on next page)

(continued from previous page)

```

default Cmd exerciseBar_SomeChoice(Bar_SomeChoice arg) { /* ... */ }

default Cmd exerciseBar_SomeChoice(String aName) { /* ... */ }
}

public static class Contract extends ContractWithKey<ContractId, Bar, BarKey> {
  // inherited:
  public final ContractId id;
  public final Bar data;

  public static Contract fromCreatedEvent(CreatedEvent event) { /* ... */ }
}

public static final class CreateAnd
  extends com.daml.ledger.javaapi.data.codegen.CreateAnd
  implements Exercises<CreateAndExerciseCommand> { /* ... */ }

public static final class ByKey
  extends com.daml.ledger.javaapi.data.codegen.ByKey
  implements Exercises<ExerciseByKeyCommand> { /* ... */ }
}

```

Note that `byKey` and `ByKey` will only be generated for templates that define a key.

Variants (a.k.a Sum Types)

A *variant or sum type* is a type with multiple constructors, where each constructor wraps a value of another type. The generated code is comprised of an abstract class for the variant type itself and a subclass thereof for each constructor. Classes for variant constructors are similar to classes for records.

Listing 8: Com/Acme/Variants.daml

```

module Com.Acme.Variants where

data BookAttribute = Pages Int
                  | Authors [Text]
                  | Title Text
                  | Published with year: Int; publisher: Text

```

The Java code generated for this variant is:

Listing 9: com/acme/variants/BookAttribute.java

```

package com.acme.variants;

public class BookAttribute extends Variant<BookAttribute> {
  public static BookAttribute fromValue(Value value) { /* ... */ }

  public static BookAttribute fromValue(Value value) { /* ... */ }
  public abstract Variant toValue();
}

```

Listing 10: com/acme/variants/bookattribute/Pages.java

```
package com.acme.variants.bookattribute;

public class Pages extends BookAttribute {
    public final Long longValue;

    public static Pages fromValue(Value value) { /* ... */ }

    public Pages(Long longValue) { /* ... */ }
    public Variant toValue() { /* ... */ }
}
```

Listing 11: com/acme/variants/bookattribute/Authors.java

```
package com.acme.variants.bookattribute;

public class Authors extends BookAttribute {
    public final List<String> listValue;

    public static Authors fromValue(Value value) { /* ... */ }

    public Author(List<String> listValue) { /* ... */ }
    public Variant toValue() { /* ... */ }
}
```

Listing 12: com/acme/variants/bookattribute/Title.java

```
package com.acme.variants.bookattribute;

public class Title extends BookAttribute {
    public final String stringValue;

    public static Title fromValue(Value value) { /* ... */ }

    public Title(String stringValue) { /* ... */ }
    public Variant toValue() { /* ... */ }
}
```

Listing 13: com/acme/variants/bookattribute/Published.java

```
package com.acme.variants.bookattribute;

public class Published extends BookAttribute {
    public final Long year;
    public final String publisher;

    public static Published fromValue(Value value) { /* ... */ }

    public Published(Long year, String publisher) { /* ... */ }
    public Variant toValue() { /* ... */ }
}
```

Enums

An enum type is a simplified [sum type](#) with multiple constructors but without argument nor type parameters. The generated code is standard java Enum whose constants map enum type constructors.

Listing 14: Com/Acme/Enum.daml

```
module Com.Acme.Enum where

data Color = Red | Blue | Green
```

The Java code generated for this variant is:

Listing 15: com/acme/enum/Color.java

```
package com.acme.enum;

public enum Color implements DamlEnum<Color> {
    RED,
    GREEN,
    BLUE;

    /* ... */
    public static final Color fromValue(Value value$) { /* ... */ }
    public final DamlEnum toValue() { /* ... */ }
}
```

Parameterized Types

Note: This section is only included for completeness. The `fromValue` and `toValue` methods would typically come from a template that doesn't have any unbound type parameters.

The Java codegen uses Java Generic types to represent [Daml parameterized types](#).

This Daml fragment defines the parameterized type `Attribute`, used by the `BookAttribute` type for modeling the characteristics of the book:

Listing 16: Com/Acme/ParameterizedTypes.daml

```

module Com.Acme.ParameterizedTypes where

data Attribute a = Attribute
  with v : a

data BookAttributes = BookAttributes with
  pages : (Attribute Int)
  authors : (Attribute [Text])
  title : (Attribute Text)

```

The Java codegen generates a Java file with a generic class for the `Attribute a` data type:

Listing 17: com/acme/parameterizedtypes/Attribute.java

```

package com.acme.parameterizedtypes;

public class Attribute<a> {
  public final a value;

  public Attribute(a value) { /* ... */ }

  public DamlRecord toValue(Function<a, Value> toValuea) { /* ... */ }

  public static <a> Attribute<a> fromValue(Value value$, Function<Value, a>
  ↪fromValuea) { /* ... */ }
}

```

Convert a Value of a Generated Type to a Java Bindings Value

To convert an instance of the generic type `Attribute<a>` to a Java Bindings [Value](#), call the `toValue` method and pass a function as the `toValuea` argument for converting the field of type `a` to the respective Java Bindings [Value](#). The name of the parameter consists of `toValue` and the name of the type parameter, in this case `a`, to form the name `toValuea`.

Below is a Java fragment that converts an attribute with a `java.lang.Long` value to the Java Bindings representation using the method reference `Int64::new`.

```

Attribute<Long> pagesAttribute = new Attributes<>(42L);

Value serializedPages = pagesAttribute.toValue(Int64::new);

```

See [Daml To Java Type Mapping](#) for an overview of the Java Bindings [Value](#) types.

Note: If the Daml type is a record or variant with more than one type parameter, you need to pass a conversion function to the `toValue` method for each type parameter.

Create a Value of a Generated Type from a Java Bindings Value

Analogous to the `toValue` method, to create a value of a generated type, call the method `fromValue` and pass conversion functions from a Java Bindings `Value` type to the expected Java type.

```
Attribute<Long> pagesAttribute = Attribute.<Long>fromValue(serializedPages,
    f -> f.asInt64().getOrElseThrow(() -> throw new IllegalArgumentException(
↳ "Expected Int field").getValue()));
```

See Java Bindings `Value` class for the methods to transform the Java Bindings types into corresponding Java types.

Non-exposed Parameterized Types

If the parameterized type is contained in a type where the actual type is specified (as in the `BookAttributes` type above), then the conversion methods of the enclosing type provides the required conversion function parameters automatically.

Convert Optional Values

The conversion of the Java `Optional` requires two steps. The `Optional` must be mapped in order to convert its contains before to be passed to `DamlOptional::of` function.

```
Attribute<Optional<Long>> idAttribute = new Attribute<List<Long>>(Optional.
↳ of(42));

val serializedId = DamlOptional.of(idAttribute.map(Int64::new));
```

To convert back `DamlOptional` to Java `Optional`, one must use the containers method `toOptional`. This method expects a function to convert back the value possibly contains in the container.

```
Attribute<Optional<Long>> idAttribute2 =
    serializedId.toOptional(v -> v.asInt64().orElseThrow(() -> new
↳ IllegalArgumentException("Expected Int64 element")));
```

Convert Collection Values

`DamlCollectors` provides collectors to converted Java collection containers such as `List` and `Map` to `DamlValues` in one pass. The builders for those collectors require functions to convert the element of the container.

```
Attribute<List<String>> authorsAttribute =
    new Attribute<List<String>>(Arrays.asList("Homer", "Ovid", "Vergil"));

Value serializedAuthors =
    authorsAttribute.toValue(f -> f.stream().collect(DamlCollector.
↳ toList(Text::new));
```

To convert back `Daml` containers to Java ones, one must use the containers methods `toList` or `toMap`. Those methods expect functions to convert back the container's entries.

```

Attribute<List<String>> authorsAttribute2 =
  Attribute.<List<String>>fromValue(
    serializedAuthors,
    f0 -> f0.asList().orElseThrow(() -> new IllegalArgumentException(
      ↪"Expected DamlList field"))
      .toList(
        f1 -> f1.asText().orElseThrow(() -> new IllegalArgumentException(
          ↪"Expected Text element"))
          .getValue()
        )
    );

```

Daml Interfaces

From this daml definition:

Listing 18: Interfaces.daml

```

module Interfaces where

data TifView = TifView { name : Text }

interface Tif where
  viewtype TifView
  getOwner: Party
  dup: Update (ContractId Tif)
  choice Ham: ContractId Tif with
    controller getOwner this
    do dup this
  choice Useless: ContractId Tif with
    interfacely: ContractId Tif
    controller getOwner this
    do
      dup this

template Child
  with
    party: Party
  where
    signatory party
    choice Bar: () with
      controller party
      do
        return ()

    interface instance Tif for Child where
      view = TifView "Child"
      getOwner = party
      dup = toInterfaceContractId <$> create this

```

The generated file for the interface definition can be seen below. Effectively it is a class that contains only the inner type ContractId because one will always only be able to deal with Interfaces via their ContractId.

Listing 19: interfaces/Tif.java

```

package interfaces

/* imports */

public final class Tif {
    public static final Identifier TEMPLATE_ID = new Identifier(
        ↪ "94fb4fa48ceflec7d474ff3d6883a00b2f337666c302ec5e2b87e986da5c27a3", "Interfaces
        ↪ ", "Tif");

    public static final Choice<TIf, Transfer, ContractId> CHOICE_Transfer =
        Choice.create(/* ... */);

    public static final Choice<TIf, Archive, Unit> CHOICE_Archive =
        Choice.create(/* ... */);

    public static final INTERFACE INTERFACE = new INTERFACE();

    public static final class ContractId extends com.daml.ledger.javaapi.data.
        ↪ codegen.ContractId<TIf>
        implements Exercises<ExerciseCommand> {
        public ContractId(String contractId) { /* ... */ }
    }

    public interface Exercises<Cmd> extends com.daml.ledger.javaapi.data.codegen.
        ↪ Exercises<Cmd> {
        default Cmd exerciseUseless(Useless arg) { /* ... */ }

        default Cmd exerciseHam(Ham arg) { /* ... */ }
    }

    public static final class CreateAnd
        extends com.daml.ledger.javaapi.data.codegen.CreateAnd.ToInterface
        implements Exercises<CreateAndExerciseCommand> { /* ... */ }

    public static final class ByKey
        extends com.daml.ledger.javaapi.data.codegen.ByKey.ToInterface
        implements Exercises<ExerciseByKeyCommand> { /* ... */ }

    public static final class INTERFACE extends InterfaceCompanion<TIf> { /* ... */ }
}

```

For templates the code generation will be slightly different if a template implements interfaces. To allow converting the `ContractId` of a template to an interface `ContractId`, an additional conversion method called `toInterface` is generated. An `unsafeFromInterface` is also generated to make the [unchecked] conversion in the other direction.

Listing 20: interfaces/Child.java

```

package interfaces

/* ... */

public final class Child extends Template {

```

(continues on next page)

(continued from previous page)

```

/* ... */

public static final class ContractId extends com.daml.ledger.javaapi.data.
↳codegen.ContractId<Child>
    implements Exercises<ExerciseCommand> {

    /* ... */

    public Tif.ContractId toInterface(Tif.INTERFACE interfaceCompanion) { /* ... */
↳*/ }

    public static ContractId unsafeFromInterface(Tif.ContractId
↳interfaceContractId) { /* ... */ }

}

public interface Exercises<Cmd> extends com.daml.ledger.javaapi.data.codegen.
↳Exercises<Cmd> {
    default Cmd exerciseBar(Bar arg) { /* ... */ }

    default Cmd exerciseBar() { /* ... */ }
}

/* ... */
}

```

12.5.5.6 Java Bindings Example Project

To try out the Java bindings library, use the [PingPong example on GitHub](#): PingPongReactive.

The example implements the PingPong application, which consists of:

- a Daml model with two contract templates, Ping and Pong
- two parties, Alice and Bob

The logic of the application goes like this:

1. The application injects a contract of type Ping for Alice.
2. Alice sees this contract and exercises the consuming choice RespondPong to create a contract of type Pong for Bob.
3. Bob sees this contract and exercises the consuming choice RespondPing to create a contract of type Ping for Alice.
4. Points 2 and 3 are repeated until the maximum number of contracts defined in the Daml is reached.

Set Up the Example Projects

To set up the example projects, clone the public GitHub repository at github.com/digital-asset/ex-java-bindings and follow the setup instructions in the [PingPong project README file](#).

This project contains two examples of the PingPong application, built directly with gRPC and using the RxJava2-based Java bindings.

Example Project

PingPongMain.java

The entry point for the Java code is the main class `src/main/java/examples/pingpong/grpc/PingPongMain.java`. Look at this class to see:

- how to connect to and interact with a Daml Ledger via the Java bindings
- how to use the Reactive layer to build an automation for both parties.

At high level, the code does the following steps:

- creates an instance of `DamlLedgerClient` connecting to an existing Ledger
- connect this instance to the Ledger with `DamlLedgerClient.connect()`
- create two instances of `PingPongProcessor`, which contain the logic of the automation (This is where the application reacts to the new `Ping` or `Pong` contracts.)
- run the `PingPongProcessor` forever by connecting them to the incoming transactions
- inject some contracts for each party of both templates
- wait until the application is done

PingPongProcessor.runIndefinitely()

The core of the application is the `PingPongProcessor.runIndefinitely()`.

The `PingPongProcessor` queries the transactions first via the `TransactionsClient` of the `DamlLedgerClient`. Then, for each transaction, it produces `Commands` that will be sent to the Ledger via the `CommandSubmissionClient` of the `DamlLedgerClient`.

Output

The application prints statements similar to these:

```
Bob is exercising RespondPong on #1:0 in workflow Ping-Alice-1 at count 0
Alice is exercising RespondPing on #344:1 in workflow Ping-Alice-7 at count 9
```

The first line shows that:

- Bob is exercising the `RespondPong` choice on the contract with ID `#1:0` for the workflow `Ping-Alice-1`.
- Count `0` means that this is the first choice after the initial `Ping` contract.
- The workflow ID `Ping-Alice-1` conveys that this is the workflow triggered by the second initial `Ping` contract that was created by Alice.

The second line is analogous to the first one.

12.5.5.7 IOU Quickstart Tutorial

In this guide, you will learn about developer tools and Daml applications by:

- developing a simple ledger application for issuing, managing, transferring and trading IOUs (I Owe You!)
- developing an integration layer that exposes some of the functionality via custom REST services

Prerequisites:

- You understand what an IOU is. If you are not sure, read the [IOU tutorial overview](#).
- You have installed the SDK. See [installation](#).

Download the Quickstart Application

You can get the quickstart application using the Daml assistant (daml):

1. Run `daml new quickstart --template quickstart-java`
This creates the `quickstart-java` application into a new folder called `quickstart`.
2. Run `cd quickstart` to change into the new directory.

Folder Structure

The project contains the following files:

```

.
├── daml
│   ├── Iou.daml
│   ├── IouTrade.daml
│   ├── Main.daml
│   └── Tests
│       ├── Iou.daml
│       └── Trade.daml
├── daml.yaml
├── frontend-config.js
├── pom.xml
├── src
│   ├── main
│   │   ├── java
│   │   │   ├── com
│   │   │   │   ├── daml
│   │   │   │   │   ├── quickstart
│   │   │   │   │   │   ├── iou
│   │   │   │   │   │   │   IouMain.java
│   │   └── resources
│   │       └── logback.xml

```

`daml.yaml` is a Daml project config file used by the SDK to find out how to build the Daml project and how to run it.

`daml` contains the [Daml code](#) specifying the contract model for the ledger.

`daml/Tests` contains [test scripts](#) for the Daml model.
`frontend-config.js` is a configuration file for the [Navigator \(Deprecated\)](#) frontend.
`pom.xml` and `src/main/java` constitute a [Java application](#) that provides REST services to interact with the ledger.

You will explore these in more detail through the rest of this guide.

Understand IOUs

To run through this guide, you will need to understand what an IOU is. This section describes the properties of an IOU like a bank bill that make it useful as a representation and transfer of value.

A bank bill represents a contract between the owner of the bill and its issuer, the central bank. Historically, it is a bearer instrument - it gives anyone who holds it the right to demand a fixed amount of material value, often gold, from the issuer in exchange for the note.

To do this, the note must have certain properties. In particular, the British pound note shown below illustrates the key elements that are needed to describe money in Daml:

1) The Legal Agreement

For a long time, money was backed by physical gold or silver stored in a central bank. The British pound note, for example, represented a promise by the central bank to provide a certain amount of gold or silver in exchange for the note. This historical artifact is still represented by the following statement:

I promise to pay the bearer on demand the sum of five pounds.

The true value of the note comes from the fact that it physically represents a bearer right that is matched by an obligation on the issuer.

2) The Signature of the Counterparty

The value of a right described in a legal agreement is based on a matching obligation for a counterparty. The British pound note would be worthless if the central bank, as the issuer, did not recognize its obligation to provide a certain amount of gold or silver in exchange for the note. The chief cashier confirms this obligation by signing the note as a delegate for the Bank of England. In general, determining the parties that are involved in a contract is key to understanding its true value.

3) The Security Token

Another feature of the pound note is the security token embedded within the physical paper. It allows the note to be authenticated with limited effort by holding it against a light source. Even a third party can verify the note without requiring explicit confirmation from the issuer that it still acknowledges the associated obligations.

4) The Unique Identifier

Every note has a unique registration number that allows the issuer to track their obligations and detect duplicate bills. Once the issuer has fulfilled the obligations associated with a particular note, duplicates with the same identifier automatically become invalid.

5) The Distribution Mechanism

The note itself is printed on paper, and its legal owner is the person holding it. The physical form of the note allows the rights associated with it to be transferred to other parties that are not explicitly mentioned in the contract.

Run the Application Using Prototyping Tools

In this section, you will run the quickstart application and get introduced to the main tools for prototyping Daml:

1. To compile the Daml model, run `daml build`

This creates a DAR file (DAR is just the format that Daml compiles to) called `.daml/dist/quickstart-0.0.1.dar`. The output should look like this:

```
2022-09-08 14:33:41.65 [INFO] [build]
Compiling quickstart to a DAR.

2022-09-08 14:33:42.90 [INFO] [build]
Created .daml/dist/quickstart-0.0.1.dar
```

2. To run the [sandbox](#) (a lightweight local version of the ledger), run:

```
daml sandbox --port 6865
```

3. In a separate terminal run the following:

Upload the DAR file:

```
daml ledger upload-dar --host localhost --port 6865 .daml/dist/quickstart-0.0.1.dar
```

Run the init script:

```
daml script --ledger-host localhost --ledger-port 6865 --dar .daml/dist/quickstart-0.0.1.dar --script-name Main:initialize --output-file output.json
```

Start the [Navigator \(Deprecated\)](#), a browser-based ledger front-end, by running:

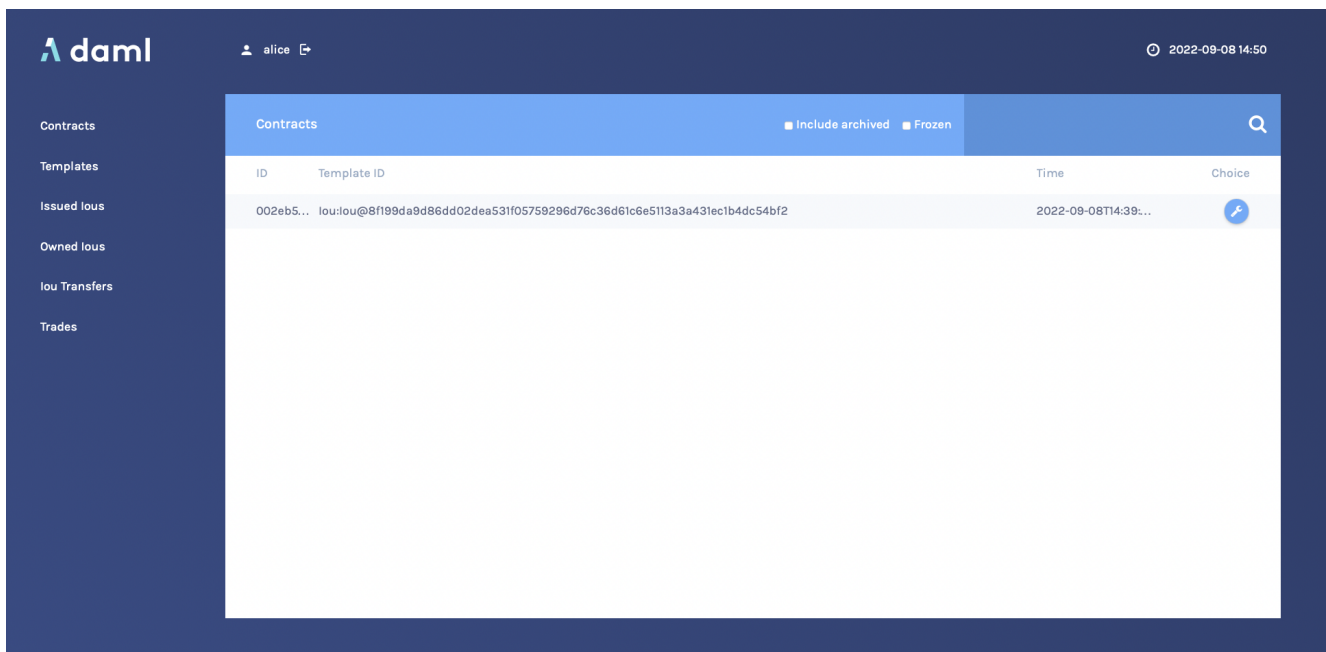

```
daml navigator server localhost 6865 --port 7500
```

The Navigator automatically connects to the sandbox. You can access it on port 7500.

Try the Application

Now everything is running, you can try out the quickstart application:

1. Go to <http://localhost:7500/>. This is the *Navigator*, which you launched *earlier*.
2. On the login screen, select *alice* from the dropdown. This logs you in as *alice*. This takes you to the contracts view:

This is showing you what contracts are currently active on the sandbox ledger and visible to *alice*. You can see that there is a single such contract, in our case with Id *002eb5...*, created from a *template* called *Iou:Iou@8f199da...*

Your contract ID will vary. The actual value doesn't matter. We'll refer to this contract as *002eb5* in the rest of this document, and you'll need to substitute your own value mentally.

3. On the left-hand side, you can see what the pages the Navigator contains:

- Contracts
- Templates
- Issued Iou
- Owned Iou
- Iou Transfers
- Trades

Contracts and **Templates** are standard views, available in any application. The others are created just for this application, specified in the `frontend-config.js` file.

For information on creating custom Navigator views, see [Customizable table views](#).

4. Click **Templates** to open the Templates page.

This displays all available *contract templates*. Instances of contracts (or just *contracts*) are created from these templates. The names of the templates are of the format *module:template@hash*. Including the hash disambiguates templates, even when identical module and template names are used between packages.

On the far right, you see the number of *contracts* that you can see for each template, if any, or – for no contract.

- Try creating a contract from a template. Issue an *lou* to yourself by clicking on the `Iou:Iou@8f199...` row, filling it out as shown below (use the provided auto-complete feature for the `Party` values in `issuer` and `owner`) and clicking **Submit**.

- On the left-hand side, click **Issued lous** to go to that page. You can see the *lou* you just issued yourself.
- Now, try transferring this *lou* to someone else. Click on your *lou*, select `Iou_Transfer`, select `Bob:...` as the new owner and hit **Submit**.
- Go to the **Owned lous** page.
The screen shows the same contract `002eb5` that you already saw on the *Contracts* page. It is an *lou* for `100`, issued by `EUR_Bank:...`.
- Go to the **lou Transfers** page. It shows the transfer of your recently issued *lou* to Bob, but Bob has not accepted the transfer, so it is not settled.
This is an important part of Daml: nobody can be forced into owning an *lou*, or indeed agreeing to any other contract. They must explicitly consent.
You could cancel the transfer by using the `IouTransfer_Cancel` choice within it, but for this walk-through, leave it alone for the time being.
- Try asking Bob to exchange your `100` for `$110`. To do so, you first have to show your *lou* to Bob so that he can verify the settlement transaction, should he accept the proposal.
Go back to **Owned lous**, open the *lou* for `100` and click on the button `Iou_AddObserver`. Select `Bob:...` as the `newObserver`.
Contracts in Daml are immutable, meaning they cannot be changed, only created and archived. If you head back to the **Owned lous** screen, you can see that the *lou* now has a new Contract ID. In our case, it's `00018fe...`.
- To propose the trade, go to the **Templates** screen. Click on the `IouTrade:IouTrade@...` template, fill in the form as shown below and submit the transaction. Remember to use the drop-down for the values of `buyer`, `seller`, `baseIouCid`, `baseIssuer`, and `quoteIssuer`.
- Go to the **Trades** page. It shows the just-proposed trade.
- You are now going to switch user to Bob, so you can accept the trades you have just proposed. Start by clicking on the logout button next to the username, at the top of the screen. On the login page, select `bob` from the dropdown.

Submit

14. First, accept the transfer of the *AliceCoin*. Go to the **Iou Transfers** page, click on the row of the transfer, and click `IouTransfer_Accept`, then **Submit**.
15. Go to the **Owned Iou** page. It now shows the *AliceCoin*.
It also shows an *Iou* for \$110 issued by `USD_Bank::...`. This matches the trade proposal you made earlier as Alice. Remember the first few characters of its Contract ID (in our case 0086c84).

daml bob 2022-09-08 15:21

Contracts

Templates

Issued Iou

Owned Iou >

Iou Transfers

Trades

Contracts include archived frozen Q

Contract ID	Issuer	Currency	Amount
002afc65d4881e5d959380d77...	Alice: 12204b8a74e8af3c81e36...	AliceCoin	1.0
0086c84c76dfc68b469b52275...	USD_Bank: 12204b8a74e8af3...	USD	110.0

16. Settle the trade. Go to the **Trades** page, and click on the row of the proposal. Accept the trade by clicking `IouTrade_Accept`. In the popup, select the Contract ID you just noted from the dropdown as the `quoteIouCid`, then click **Submit**.
The two legs of the transfer are now settled atomically in a single transaction. The trade either

fails or succeeds as a whole.

17. Privacy is an important feature of Daml. You can check that Alice and Bob's privacy relative to the Banks was preserved.

To do this, log out, then log in as `us`, which maps to `USD_Bank: : . . .`.

On the **Contracts** page, select **Include archived**. The page now shows all the contracts that `USD_Bank: : . . .` has ever known about.

There are just five contracts:

Three contracts created on startup:

1. A self-issued *lou* for \$110.
2. The *louTransfer* to transfer that *lou* to Bob
3. The resulting *lou* owned by Bob.

The transfer of Bob's *lou* to Alice that happened as part of the trade. Note that this is a transient contract that got archived in the same transaction it got created in.

The new \$110 *lou* owned by Alice. This is the only active contract.

Importantly, `USD_Bank: : . . .` does not know anything about the trade or the EUR-leg. It has no idea what was exchanged for those \$110, or indeed if anything was exchanged at all. For more information on privacy, refer to the [Daml Ledger Model Concepts](#).

Note: `USD_Bank: : . . .` does know about an intermediate *louTransfer* contract that was created and consumed as part of the atomic settlement in the previous step. Since that contract was never active on the ledger, it is not shown in Navigator. You will see how to view a complete transaction graph, including who knows what, in [Test Using Daml Script](#) below.

Get Started with Daml

The *contract model* specifies the possible contracts, as well as the allowed transactions on the ledger, and is written in Daml.

The core concept in Daml is a *contract template* - you used them earlier to create contracts. Contract templates specify:

- a type of contract that may exist on the ledger, including a corresponding data type
- the *signatories*, who need to agree to the *creation* of a contract of that type
- the *rights* or *choices* given to parties by a contract of that type
- constraints or conditions on the data on a contract
- additional parties, called observers, who can see the contract

For more information about Daml Ledgers, consult [Daml Ledger Model Concepts](#) for an in-depth technical description.

Develop with Daml Studio

Take a look at the Daml that specifies the contract model in the quickstart application. The core template is `Iou`.

1. Open [Daml Studio](#), a Daml IDE based on VS Code, by running `daml studio` from the root of your project.
2. Using the explorer on the left, open `daml/Iou.daml`.

The first (uncommented, non-empty) line specifies the module name:

```
module Iou where
```

Next, a template called *Iou* is declared together with its datatype. This template has five fields:

```
template Iou
  with
    issuer : Party
    owner  : Party
    currency : Text
    amount : Decimal
    observers : [Party]
```

Conditions for the creation of a contract are specified using the *ensure* and *signatory* keywords:

```
ensure amount > 0.0

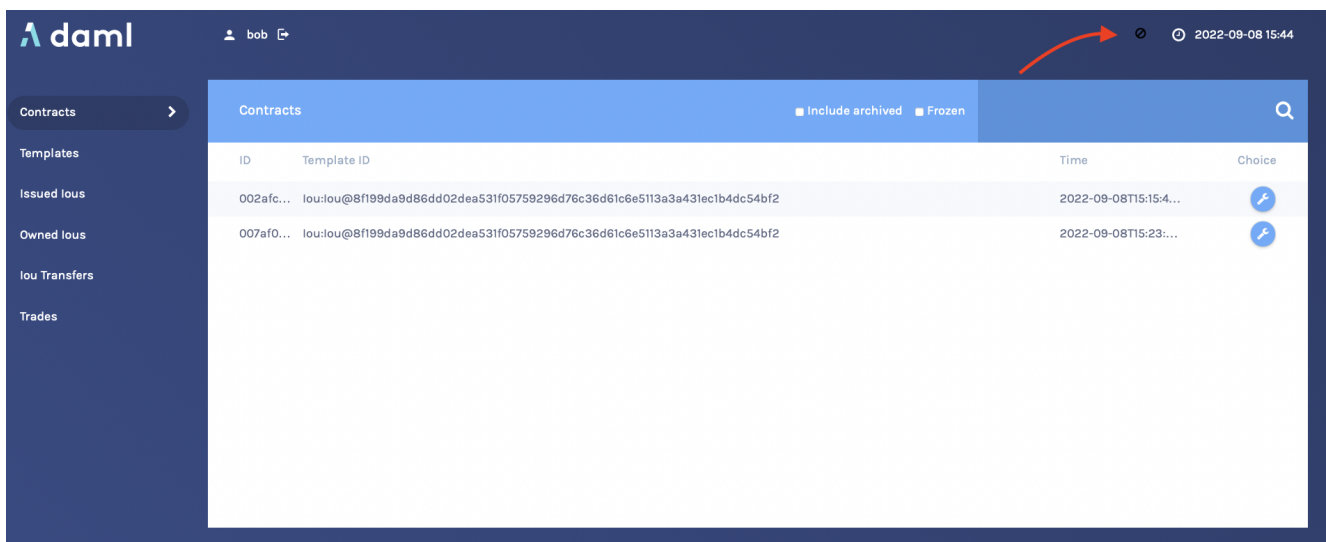

signatory issuer, owner
```

In this case, there are two conditions:

- An *Iou* can only be created if it is authorized by both *issuer* and *owner*.
- The *amount* needs to be positive.

Earlier, as Alice, you authorized the creation of an *Iou*. The *amount* was 1.0, and Alice was both *issuer* and *owner*, so both conditions were satisfied, and you could successfully create the contract.

To see this in action, go back to the Navigator and try to create the same *Iou* again, but with Bob as *owner* (with Alice as *issuer*). It will not work. Note that the Navigator shows success or failures as a small icon in the top right, as highlighted here (it would be a small *v* for success):

Observers are specified using the *observer* keyword:

```
observer observers
```

Here, *observer* is the keyword and *observers* refers to the field of the template.

Next, the *rights* or *choices* are defined, in this case with *owner* as the controller:

```

choice Iou_Split : (IouCid, IouCid)
  with
    splitAmount: Decimal
  controller owner
  do
    let restAmount = amount - splitAmount
    splitCid <- create this with amount = splitAmount
    restCid <- create this with amount = restAmount
    return (splitCid, restCid)

```

```

choice Iou_Merge : IouCid
  with
    otherCid: IouCid
  controller owner
  do
    otherIou <- fetch otherCid
    -- Check the two IOU's are compatible
    assert (
      currency == otherIou.currency &&
      owner == otherIou.owner &&
      issuer == otherIou.issuer
    )
    -- Retire the old Iou
    archive otherCid
    -- Return the merged Iou
    create this with amount = amount + otherIou.amount

```

```

choice Iou_Transfer : ContractId IouTransfer
  with
    newOwner : Party
  controller owner
  do create IouTransfer with iou = this; newOwner

```

```

choice Iou_AddObserver : IouCid
  with
    newObserver : Party
  controller owner
  do create this with observers = newObserver :: observers

choice Iou_RemoveObserver : IouCid
  with
    oldObserver : Party
  controller owner
  do create this with observers = filter (/= oldObserver) observers

```

Thus, owner has the right to:

- Split the Iou.
- Merge it with another one differing only on amount.
- Initiate a transfer.
- Add and remove observers.

The `Iou_Transfer` choice above takes a parameter called `newOwner` and creates a new `IouTransfer` contract and returns its `ContractId`. It is important to know that, by default, choices consume the contract on which they are exercised. Consuming, or archiving, makes the contract no longer active. So the `IouTransfer` replaces the `Iou`.

A more interesting choice is `IouTrade_Accept`. To look at it, open `IouTrade.daml`.

```
choice IouTrade_Accept : (IouCid, IouCid)
with
  quoteIouCid : IouCid
controller seller
do
  baseIou <- fetch baseIouCid
  baseIssuer === baseIou.issuer
  baseCurrency === baseIou.currency
  baseAmount === baseIou.amount
  buyer === baseIou.owner
  quoteIou <- fetch quoteIouCid
  quoteIssuer === quoteIou.issuer
  quoteCurrency === quoteIou.currency
  quoteAmount === quoteIou.amount
  seller === quoteIou.owner
  quoteIouTransferCid <- exercise quoteIouCid Iou_Transfer with
    newOwner = buyer
  transferredQuoteIouCid <- exercise quoteIouTransferCid IouTransfer_Accept
  baseIouTransferCid <- exercise baseIouCid Iou_Transfer with
    newOwner = seller
  transferredBaseIouCid <- exercise baseIouTransferCid IouTransfer_Accept
  return (transferredQuoteIouCid, transferredBaseIouCid)
```

This choice uses the `===` operator from the [Daml Standard Library](#) to check pre-conditions. The standard library is imported using `import DA.Assert` at the top of the module.

Then, it composes the `Iou_Transfer` and `IouTransfer_Accept` choices to build one big transaction. In this transaction, `buyer` and `seller` exchange their lous atomically, without disclosing the entire transaction to all parties involved.

The *Issuers* of the two lous, which are involved in the transaction because they are signatories on the `Iou` and `IouTransfer` contracts, only get to see the sub-transactions that concern them, as we saw earlier.

For a deeper introduction to Daml, consult the [Daml Reference](#).

Test Using Daml Script

You can check the correct authorization and privacy of a contract model using *scripts*: tests that are written in Daml.

Scripts are a linear sequence of transactions that is evaluated using the same consistency, conformance and authorization rules as it would be on the full ledger server or the sandbox ledger. They are integrated into Daml Studio, which can show you the resulting transaction graph, making them a powerful tool to test and troubleshoot the contract model.

To take a look at the scripts in the quickstart application, open `daml/Tests/Trade.daml` in Daml Studio.

A script test is defined with `trade_test = script do`. The `submit` function takes a submitting party and a transaction, which is specified the same way as in contract choices.

The following block, for example, issues an `Iou` and transfers it to Alice:

```
-- Banks issue IOU transfers.
iouTransferAliceCid <- submit eurBank do
  createAndExerciseCmd
  Iou with
    issuer = eurBank
    owner = eurBank
    currency = "EUR"
    amount = 100.0
    observers = []
  Iou_Transfer with
    newOwner = alice
```

Compare the script with the `initialize` script in `daml/Main.daml`. You will see that the script you used to initialize the sandbox is an initial segment of the `trade_test` script. The latter adds transactions to perform the trade you performed through Navigator, and a couple of transactions in which expectations are verified.

After a short time, the text *Script results* should appear above the test. Click on it (in `daml/Tests/Trade.daml`) to open the visualization of the resulting ledger state.

lou:lou									
id	status	issuer	owner	currency	amount	observers	Alice	Bob	EUR_Bank
#6:6	active	'USD_Bank'	'Alice'	"USD"	110.0000000000	□	X	X	-
#6:10	active	'EUR_Bank'	'Bob'	"EUR"	100.0000000000	□	X	X	-

Each row shows a contract on the ledger. The last four columns show which parties know of which contracts. The remaining columns show the data on the contracts. You can see past contracts by checking the **Show archived** box at the top. Click the adjacent **Show transaction view** button to switch to a view of the entire transaction tree.

In the transaction view, transaction 6 is of particular interest, as it shows how the lous are exchanged atomically in one transaction. The lines starting `disclosed to` (since) show that the Banks do indeed not know anything they should not:

```
TX 6 1970-01-01T00:00:00Z (Tests.Trade:70:14)
#6:0
| disclosed to (since): 'Alice' (6), 'Bob' (6)
|> 'Bob' exercises IouTrade_Accept on #5:0 (IouTrade:IouTrade)
|   with

    |     amount = 100.0000000000;
    |     observers = []

```

The `submit` function used in this script tries to perform a transaction and fails if any of the ledger integrity rules are violated. There is also a `submitMustFail` function, which checks that certain transactions are not possible. This is used in `daml/Tests/Iou.daml`, for example, to confirm that the ledger model prevents double spends.

Integrate With the Ledger

A distributed ledger only forms the core of a full Daml application.

To build automations and integrations around the ledger, Daml has [language bindings](#) for the Ledger API in several programming languages.

To compile the Java integration for the quickstart application, we first need to run the Java codegen on the DAR we built before:

```
daml codegen java
```

Once the code has been generated (into `target/generated-sources` per the instructions in `daml.yaml`), we can compile it using:

```
mvn compile
```

Now, start the Java integration with:

```
mvn exec:java@run-quickstart -Dparty=$(cat output.json | sed 's/\[""/"/' | sed 's/
↪ ".*//')
```

Note that this step requires that the sandbox started [earlier](#) is still running. If it is not, you'll have to run the `daml sandbox` and `daml script` commands again to get an `output.json` in sync with the new state of the sandbox (party names can change with each sandbox restart).

The application provides REST services on port 8080 to perform basic operations on behalf on Alice. For example, check that:

```
curl http://localhost:8080/iou
```

returns, for a newly-created sandbox (where you have just run the `init` script to get the `output.json` file), something like:

```
{
  "0": {
    "issuer": "EUR_Bank::NAMESPACE",
    "owner": "Alice::NAMESPACE",
    "currency": "EUR",
    ↪ "amount": 100.0000000000,
    "observers": []
  }
}
```

If you still have the same sandbox running against which you have run the Navigator steps above, the output might look more like:

```
{ "0": { "issuer": "Alice::NAMESPACE", "owner": "Bob::NAMESPACE", "currency": "AliceCoin",
↪ "amount": 1.0000000000, "observers": [] }, "1": { "issuer": "USD_Bank::NAMESPACE", "owner"
↪ ": "Alice::NAMESPACE", "currency": "USD", "amount": 110.0000000000, "observers": [] } }
```

To start the same application on another port, use the command-line parameter `-Drestport=PORT`. To start it for another party, use `-Dparty=PARTY`. For example, to start the application for Bob on 8081, run:

```
mvn exec:java@run-quickstart -Drestport=8081 -Dparty=Bob $(cat output.json | sed
↪ 's/\["\|"/' | sed 's/"./'')
```

The following REST services are included:

GET on `http://localhost:8080/iou` lists all active ious, and their Ids.

Note that the Ids exposed by the REST API are not the ledger contract Ids, but integers. You can open the address in your browser or run `curl -X GET http://localhost:8080/iou`.

GET on `http://localhost:8080/iou/ID` returns the iou with Id ID.

For example, to get the content of the iou with Id 0, run:

```
curl -X GET http://localhost:8080/iou/0
```

PUT on `http://localhost:8080/iou` creates a new iou on the ledger.

To create another *AliceCoin*, run:

```
curl -X PUT -d '{"issuer": "Alice::NAMESPACE", "owner": "Alice::NAMESPACE",
↪ "currency": "AliceCoin", "amount": 1.0, "observers": []}' http://localhost:8080/
↪ iou
```

Note that you have to replace `NAMESPACE` with the real namespace assigned by the sandbox; you can find it in `output.json`:

```
ns=$(cat output.json | sed 's/\["\|"/' | sed 's/"./'); curl -X PUT -d
↪ "$ (printf '{"issuer": "Alice::%s", "owner": "Alice::%s", "currency": "AliceCoin",
↪ "amount": 1.0, "observers": []}' $ns $ns) " http://localhost:8080/iou
```

POST on `http://localhost:8080/iou/ID/transfer` transfers the iou with Id ID.

Check the index of your new *AliceCoin* by listing all active ious. If you have just run the init script, it will be 0; if you have run the Navigator section, it will likely be 2. Once you have the index, you can run:

```
ns=$(cat output.json | sed 's/\["\|"/' | sed 's/"./'); curl -X POST -
↪ -d '{"newOwner": "Bob::%s"}' http://localhost:8080/iou/0/transfer
```

to transfer it to Bob. If it's not 0, just replace the 0 in `iou/0` in the above command.

The automation is based on the [Java bindings](#) and the output of the [Java code generator](#), which are included as a Maven dependency and Maven plugin respectively in the `pom.xml` file created by the template:

```
<dependency>
  <groupId>com.daml</groupId>
  <artifactId>bindings-rxjava</artifactId>
  <version>__VERSION__</version>
  <exclusions>
    <exclusion>
      <groupId>com.google.protobuf</groupId>
```

(continues on next page)

(continued from previous page)

```

        <artifactId>protobuf-lite</artifactId>
      </exclusion>
    </exclusions>
  </dependency>

```

It consists of the application in file `IouMain.java`. It uses the class `Iou` from `Iou.java`, which is generated from the Daml model with the Java code generator. The `Iou` class provides better serialization and de-serialization to JSON via [gson](#). Looking at `src/main/java/com/daml/quickstart/iou/IouMain.java`:

1. A connection to the ledger is established using a `DamlLedgerClient` object.

```

DamlLedgerClient client = DamlLedgerClient.newBuilder(ledgerhost, ledgerport)
    .build();

// Connects to the ledger and runs initial validation.
client.connect();

```

2. An in-memory contract store is initialized. This is intended to provide a live view of all active contracts, with mappings between ledger and external ids.

```

ConcurrentHashMap<Long, Iou> contracts = new ConcurrentHashMap<>();
BiMap<Long, Iou.ContractId> idMap = Maps.synchronizedBiMap(HashBiMap
    .create());
AtomicReference<LedgerOffset> acsOffset =
    new AtomicReference<>(LedgerOffset.LedgerBegin.getInstance());

```

3. The Active Contracts Service (ACS) is used to quickly build up the contract store to a recent state.

```

client
    .getActiveContractSetClient()
    .getActiveContracts(Iou.contractFilter(), Collections.singleton(party),
        true)
    .blockingForEach(
        response -> {
            response.offset.ifPresent(offset -> acsOffset.set(new LedgerOffset.
                Absolute(offset)));
            response.activeContracts.forEach(
                contract -> {
                    long id = idCounter.getAndIncrement();
                    contracts.put(id, contract.data);
                    idMap.put(id, contract.id);
                });
        });

```

`blockingForEach` is used to ensure that the contract store is consistent with the ledger state at the latest offset observed by the client.

4. The Transaction Service is wired up to update the contract store on occurrences of `ArchiveEvent` and `CreateEvent` for ious. Since `getTransactions` is called without end offset, it will stream transactions indefinitely, until the application is terminated.

```

client
    .getTransactionsClient()
    .getTransactions(
        Iou.contractFilter(), acsOffset.get(), Collections.
        singleton(party), true)

```

(continues on next page)

(continued from previous page)

```

        .forEach(
            t -> {
                for (Event event : t.getEvents()) {
                    if (event instanceof CreatedEvent) {
                        CreatedEvent createdEvent = (CreatedEvent) event;
                        long id = idCounter.getAndIncrement();
                        Iou.Contract contract = Iou.Contract.
↪fromCreatedEvent(createdEvent);
                        contracts.put(id, contract.data);
                        idMap.put(id, contract.id);
                    } else if (event instanceof ArchivedEvent) {
                        ArchivedEvent archivedEvent = (ArchivedEvent) event;
                        long id =
                            idMap.inverse().get(new Iou.ContractId(archivedEvent.
↪getContractId()));
                        contracts.remove(id);
                        idMap.remove(id);
                    }
                }
            }
        );

```

5. Commands are submitted via the Command Submission Service.

```

var params = UpdateSubmission.create(APP_ID, randomUUID().toString(),
↪update).withActAs(party);

return client.getCommandClient().submitAndWaitForResult(params).
↪blockingGet();

```

You can find examples of Update instantiations for creating contract and exercising a choice in the bodies of the transfer and iou endpoints, respectively.

Listing 21: Exercise a choice

```

Map m = g.fromJson(req.body(), Map.class);
Iou.ContractId contractId = idMap.get(Long.parseLong(req.params("id")));
var update = contractId.exerciseIou_Transfer(m.get("newOwner").toString());

```

Listing 22: Create a contract

```
Iou iou = g.fromJson(req.body(), Iou.class);
var iouCreate = iou.create();
var createdContractId = submit(client, party, iouCreate);
```

The rest of the application sets up the REST services using [Spark Java](#), and does dynamic package Id detection using the Package Service. The latter is useful during development when package Ids change frequently.

For a discussion of ledger application design and architecture, take a look at [Application Architecture Guide](#).

Next Steps

Great - you've completed the quickstart guide!

Some steps you could take next include:

- Explore [examples](#) for guidance and inspiration.

- [Learn Daml](#).

- [Language reference](#).

- Learn more about [application development](#).

- Learn about the [conceptual models](#) behind Daml.

12.5.5.8 Open Tracing in Ledger API Client Applications

Introduction

Distributed tracing is a technique used for troubleshooting performance issues in a microservices environment like Daml Enterprise. Tracing in Canton has been described in a [page dedicated to monitoring](#). This guide describes how to write **Ledger API** client applications so that distributed traces and spans can seamlessly continue between the client and Canton software components.

To study a **Ledger API** client application with OpenTelemetry support in detail, see this [example on GitHub](#).

The example implements a variation of the already familiar `PingPong` application where every call to the **Ledger API** is decorated with an OpenTelemetry trace context and demonstrates how to retrieve the trace context from past transactions.

To familiarize yourself with the broader topic of open tracing, consult the official pages of [the OpenTelemetry project](#). To find out more about open tracing in Java, the documentation on [Java OpenTelemetry instrumentation](#) is an excellent source of references and examples.

Set Up an OpenTelemetry Environment

To observe distributed tracing in action, you first need to start an OpenTelemetry backend server. Canton supports Jaeger, Zipkin, or OTLP formats. To start a Jaeger server you can use the following docker command:

```
docker run --rm -it --name jaeger\  
-p 16686:16686 \  
-p 14250:14250 \  
jaegertracing/all-in-one:1.22.0
```

You also have to start Canton with OpenTelemetry exporting enabled. You can achieve it by defining a new `jaeger.conf` configuration file:

```
canton.monitoring.tracing.tracer.exporter {  
  type = jaeger  
  address = "localhost" // it's the default, so can be omitted  
  port = 14250 // it's the default, so can be omitted  
}
```

Next, launch a small Canton installation combining the `jaeger.conf` into the configuration mix:

```
bin/canton -c examples/01-simple-topology/simple-topology.conf -c jaeger.conf
```

Add Project Dependencies

To use the OpenTelemetry libraries, add the following **Maven** dependencies to your project's `pom.xml`:

```
<dependency>  
  <groupId>io.opentelemetry</groupId>  
  <artifactId>opentelemetry-api</artifactId>  
  <version>1.29.0</version>  
</dependency>  
<dependency>  
  <groupId>io.opentelemetry</groupId>  
  <artifactId>opentelemetry-exporter-jaeger</artifactId>  
  <version>1.29.0</version>  
</dependency>  
<dependency>  
  <groupId>io.opentelemetry</groupId>  
  <artifactId>opentelemetry-sdk</artifactId>  
  <version>1.29.0</version>  
</dependency>  
<dependency>  
  <groupId>io.opentelemetry.instrumentation</groupId>  
  <artifactId>opentelemetry-grpc-1.6</artifactId>  
  <version>1.29.0-alpha</version>  
</dependency>
```

Note: Replace the version number in each dependency with the version you want to use. To find available versions, check the [Maven Central Repository](#).

Initialize

An application that wants to use OpenTelemetry must initialize a number of global controller objects that orchestrate different aspects of the distributed tracing process such as span creation, propagation, and export. The exact set of controllers needed may vary from application to application. You may draw some inspiration from the selection used in the example inside [the `OpenTelemetryUtil.createOpenTelemetry` method](#). This is the minimum set required for a fully functional Jaeger trace reporting.

The next step is to initialize the GRPCTelemetry controller, which is responsible for the propagation of the trace contexts inside the HTTP2 headers of the gRPC communication.

The example wraps the necessary initialization steps in the constructor of the `OpenTelemetryUtil` class. All you have to do is call:

```
OpenTelemetryUtil openTelemetry = new OpenTelemetryUtil(APP_ID);
```

The GRPCTelemetry controller can construct client call interceptors that need to be mounted on top of the **Netty** channels used in the gRPC communication. The example provides a useful helper method called `withClientInterceptor` that injects an interceptor at the channel builder level:

```
ManagedChannel channel = openTelemetry.withClientInterceptor(
    ManagedChannelBuilder
        .forAddress(host, port)
        .usePlaintext()
    )
    .build();
```

And with that, you are all set to start generating own spans, reporting them to the **Jaeger** server and also propagating them transparently to the **Ledger API**.

Start New Spans

Before making a gRPC call, you must generate a new span to cover the multi-component interaction that is about to be initiated. The example provides a useful combinator called `runInNewSpan` that wraps the execution of an arbitrary function in a newly generated span:

```
public <R> R runInNewSpan(String spanName, Supplier<R> body) {
    Span span = tracer.spanBuilder(spanName).startSpan();
    try (Scope ignored = span.makeCurrent()) {
        return body.get();
    } finally {
        span.end();
    }
}
```

You can use it on a command submission as follows:

```
openTelemetry.runInNewSpan("createInitialContracts", () -> submissionService.
    submit(request));
```

The gRPC interceptors that were mounted at the initialization stage do the rest of the work behind the scenes making sure that the spans make it across to the Canton.

Continue Spans Across Different Applications

Sometimes you may wish to continue the same span across multiple Daml transactions forming a single workflow. This may be especially interesting when different client application instances interact through the ledger and yet their entire conversation should be seen as a single coherent succession of spans. In that case, it is possible to extract the trace context associated with the past transactions from the `Transaction`, `TransactionTree`, or `Completion` records that are returned from the following **Ledger API** calls:

```
TransactionService.GetTransactions  
TransactionService.GetTransactionTrees  
TransactionService.GetTransactionByEventId  
TransactionService.GetTransactionById  
TransactionService.GetFlatTransactionByEventId  
TransactionService.GetFlatTransactionById  
CompletionService.CompletionStream
```

You can extract the context by using a helper function implemented in the example:

```
Context extractedContext = openTelemetry.contextFromDamlTraceContext(tx.  
↪getTraceContext());
```

The extracted context then has to be elevated to the status of the current context. Doing this allows the continuation of the original trace context into the present operation. Again the example provides a convenient combinator for that:

```
openTelemetry.runInOpenTelemetryScope(extractedContext, () -> ... );
```

Finally, you generate a new span within the original context. You can use the already familiar `runInNewSpan` method:

```
openTelemetry.runInNewSpan("follow", () ->  
    submissionService.submit(SubmitRequest.toProto(ledgerId, commandsSubmission))  
)
```

Put It All Together

When the client applications follow the rules and pass the trace contexts without interruption, it becomes possible to witness the entire workflow as one long succession of spans in Jaeger UI. The span diagram collected while running the example application is shown below:

12.5.6 Python Bindings

The Python bindings (formerly known as DAZL) are a client implementation of the *Ledger API* for the Python language and are supported under the Daml Enterprise license.

The Python bindings are supported for use with Daml and with [Daml Hub](#). Documentation for the bindings can be found [here](#).

If you want to write an application for the ledger API in other languages, you'll need to use [gRPC](#) directly.

12.5.7.1 Get Started

12.5.7.2 Protobuf Reference Documentation

12.5.7.3 Example Project

1. Configure your machine to use the example by following the instructions at [Set Up a Maven Project](#).
2. Clone the [repository](#) from GitHub.
3. Follow the [setup instructions in the README](#). Use `examples.pingpong.grpc.PingPongGrpcMain` as the main class.

About the Example Project

The example shows very simply how two parties can interact via a ledger, using two Daml contract templates, `Ping` and `Pong`.

The logic of the application goes like this:

1. The application injects a contract of type `Ping` for Alice.
2. Alice sees this contract and exercises the consuming choice `RespondPong` to create a contract of type `Pong` for Bob.
3. Bob sees this contract and exercises the consuming choice `RespondPing` to create a contract of type `Ping` for Alice.
4. Points 2 and 3 are repeated until the maximum number of contracts defined in the Daml is reached.

The entry point for the Java code is the main class `src/main/java/examples/pingpong/grpc/PingPongGrpcMain.java`. Look at it to see how connect to and interact with a ledger using gRPC.

The application prints output like this:

```
Bob is exercising RespondPong on #1:0 in workflow Ping-Alice-1 at count 0
Alice is exercising RespondPing on #344:1 in workflow Ping-Alice-7 at count 9
```

The first line shows:

Bob is exercising the `RespondPong` choice on the contract with ID `#1:0` for the workflow `Ping-Alice-1`.

Count 0 means that this is the first choice after the initial `Ping` contract.

The workflow ID `Ping-Alice-1` conveys that this is the workflow triggered by the second initial `Ping` contract that was created by Alice.

This example subscribes to transactions for a single party, as different parties typically live on different participant nodes. However, if you have multiple parties registered on the same node, or are running an application against the Sandbox, you can subscribe to transactions for multiple parties in a single subscription by putting multiple entries into the `filters_by_party` field of the `TransactionFilter` message. Subscribing to transactions for an unknown party will result in an error.

12.5.7.4 Daml Types and Protobuf

For information on how Daml types and contracts are represented by the Ledger API as protobuf messages, see [How Daml Types are Translated to Protobuf](#).

12.5.7.5 Error Handling

The Ledger API generally uses the gRPC standard status codes for signaling response failures to client applications.

For more details on the gRPC standard status codes, see the [gRPC documentation](#).

Generically, on submitted commands the Ledger API responds with the following gRPC status codes:

ABORTED The platform failed to record the result of the command due to a transient server-side error (e.g. backpressure due to high load) or a time constraint violation. You can retry the submission. In case of a time constraint violation, please refer to the section [Dealing with time](#) on how to handle commands with long processing times.

DEADLINE_EXCEEDED (when returned by the Command Service) The request might not have been processed, as its deadline expired before its completion was signalled.

ALREADY_EXISTS The command was rejected because the resource (e.g. contract key) already exists or because it was sent within the deduplication period of a previous command with the same change ID.

NOT_FOUND The command was rejected due to a missing resources (e.g. contract key not found).

INVALID_ARGUMENT The submission failed because of a client error. The platform will definitely reject resubmissions of the same command.

FAILED_PRECONDITION The command was rejected due to an interpretation error or due to a consistency error due to races.

OK (when returned by the Command Submission Service) Assume that the command was accepted and wait for the resulting completion or a timeout from the Command Completion Service.

OK (when returned by the Command Service) You can be sure that the command was successful.

INTERNAL, UNKNOWN (when returned by the Command Service) An internal system fault occurred. Contact the participant operator for the resolution.

Aside from the standard gRPC status codes, the failures returned by the Ledger API are enriched with details meant to help the application or the application developer to handle the error autonomously (e.g. by retrying on a retryable error). For more details on the rich error details see the [Error Codes](#)

12.5.8 Ledger API Reference

The specification for the services, methods, and messages for interacting with the gRPC-based Ledger API.

`com/daml/ledger/api/v1/active_contracts_service.proto`

12.5.8.1 ActiveContractsService, v1

Allows clients to initialize themselves according to a fairly recent state of the ledger without reading through all transactions that were committed since the ledger's creation. In V2 Ledger API this service is not available anymore. Use `v2.StateService` instead.

[GetActiveContracts method, v1](#)

Returns a stream of the snapshot of the active contracts at a ledger offset. If there are no active contracts, the stream returns a single response message with the offset at which the snapshot has been taken. Clients SHOULD use the offset in the last `GetActiveContractsResponse` message to continue streaming transactions with the transaction service. Clients SHOULD NOT assume that the set of active contracts they receive reflects the state at the ledger end.

Request: [GetActiveContractsRequest](#)

Response: [GetActiveContractsResponse](#)

GetActiveContractsRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid LedgerString (as described in `value.proto`). Optional

filter: [TransactionFilter](#)

Templates to include in the served snapshot, per party. Required

verbose: [bool](#)

If enabled, values served over the API will contain more information than strictly necessary to interpret the data. In particular, setting the verbose flag to true triggers the ledger to include labels for record fields. Optional

active_at_offset: [string](#)

The offset at which the snapshot of the active contracts will be computed. Must be no greater than the current ledger end offset. Must be greater than or equal to the last pruning offset. If not set the current ledger end offset will be used. Optional

GetActiveContractsResponse message, v1

offset: [string](#)

Included only in the last message. The client should start consuming the transactions endpoint with this offset. The format of this field is described in `ledger_offset.proto`.

workflow_id: [string](#)

The workflow that created the contracts. Must be a valid LedgerString (as described in `value.proto`).

active_contracts: [CreatedEvent](#) (repeated)

The list of contracts that were introduced by the workflow with `workflow_id` at the offset. Must be a valid LedgerString (as described in `value.proto`).

`com/daml/ledger/api/v1/admin/command_inspection_service.proto`

12.5.8.2 CommandInspectionService, v1/admin

Status: experimental interface, will change before it is deemed production ready

The inspection service provides methods for the ledger administrator to look under the hood of a running system. In V2 Ledger API this service is not available.

GetCommandStatus method, v1/admin

Inquire about the status of a command. This service is used for debugging only. The command status is only tracked in memory and is not persisted. The service can be used to understand the failure status and the structure of a command. Requires admin privileges The service is alpha without backward compatibility guarantees.

Request: [GetCommandStatusRequest](#)

Response: [GetCommandStatusResponse](#)

GetCommandStatusRequest message, v1/admin

command_id_prefix: [string](#)

optional filter by command id

state: [CommandState](#)

optional filter by state

limit: [uint32](#)

optional limit of returned statuses, defaults to 100

GetCommandStatusResponse message, v1/admin

command_status: [GetCommandStatusResponse.CommandStatus](#) (repeated)

GetCommandStatusResponse.CommandStatus message, v1/admin

started: [google.protobuf.Timestamp](#)

completed: [google.protobuf.Timestamp](#)

completion: [com.daml.ledger.api.v1.Completion](#)

state: [CommandState](#)

commands: [com.daml.ledger.api.v1.Command](#) (repeated)

request_statistics: [GetCommandStatusResponse.CommandStatus.RequestStatistics](#)

updates: [GetCommandStatusResponse.CommandStatus.CommandUpdates](#)

GetCommandStatusResponse.CommandStatus.CommandUpdates message, v1/admin

created: [GetCommandStatusResponse.CommandStatus.CommandUpdates.Contract](#) (repeated)

archived: [GetCommandStatusResponse.CommandStatus.CommandUpdates.Contract](#) (repeated)

exercised: [uint32](#)

fetches: [uint32](#)

looked_up_by_key: [uint32](#)

[GetCommandStatusResponse.CommandStatus.CommandUpdates.Contract](#) message, [v1/admin](#)

template_id: [com.daml.ledger.api.v1.Identifier](#)

contract_id: [string](#)

contract_key: [com.daml.ledger.api.v1.Value](#)

[GetCommandStatusResponse.CommandStatus.RequestStatistics](#) message, [v1/admin](#)

envelopes: [uint32](#)

request_size: [uint32](#)

recipients: [uint32](#)

[CommandState](#) enum, [v1/admin](#)

STATE_UNSPECIFIED	0	This value acts as wildcard in the queries
STATE_PENDING	1	
STATE_SUCCEEDED	2	
STATE_FAILED	3	

[com/daml/ledger/api/v1/admin/config_management_service.proto](#)

12.5.8.3 [ConfigManagementService](#), [v1/admin](#)

Status: experimental interface, will change before it is deemed production ready

The ledger configuration management service provides methods for the ledger administrator to change the current ledger configuration. The services provides methods to modify different aspects of the configuration. In V2 Ledger API this service is not available anymore.

[GetTimeModel](#) method, [v1/admin](#)

Return the currently active time model and the current configuration generation.

Request: [GetTimeModelRequest](#)

Response: [GetTimeModelResponse](#)

SetTimeModel method, v1/admin

Set the ledger time model.

Request: [SetTimeModelRequest](#)

Response: [SetTimeModelResponse](#)

GetTimeModelRequest message, v1/admin

Message has no fields.

GetTimeModelResponse message, v1/admin

configuration_generation: [int64](#)

The current configuration generation. The generation is a monotonically increasing integer that is incremented on each change. Used when setting the time model.

time_model: [TimeModel](#)

The current ledger time model.

SetTimeModelRequest message, v1/admin

submission_id: [string](#)

Submission identifier used for tracking the request and to reject duplicate submissions. Required.

maximum_record_time: [google.protobuf.Timestamp](#)

Deadline for the configuration change after which the change is rejected.

configuration_generation: [int64](#)

The current configuration generation which we're submitting the change against. This is used to perform a compare-and-swap of the configuration to safeguard against concurrent modifications. Required.

new_time_model: [TimeModel](#)

The new time model that replaces the current one. Required.

SetTimeModelResponse message, v1/admin

configuration_generation: [int64](#)

The configuration generation of the committed time model.

TimeModel message, v1/admin

avg_transaction_latency: [google.protobuf.Duration](#)

The expected average latency of a transaction, i.e., the average time from submitting the transaction to a `[[WriteService]]` and the transaction being assigned a record time. Required.

min_skew: [google.protobuf.Duration](#)

The minimum skew between ledger time and record time: $lt_TX \geq rt_TX - minSkew$ Required.

max_skew: [google.protobuf.Duration](#)

The maximum skew between ledger time and record time: $lt_TX \leq rt_TX + maxSkew$ Required.

com/daml/ledger/api/v1/admin/identity_provider_config_service.proto

12.5.8.4 IdentityProviderConfigService, v1/admin

Identity Provider Config Service makes it possible for participant node administrators to setup and manage additional identity providers at runtime.

This allows using access tokens from identity providers unknown at deployment time. When an identity provider is configured, independent IDP administrators can manage their own set of parties and users. Such parties and users have a matching *identity_provider_id* defined and are inaccessible to administrators from other identity providers. A user will only be authenticated if the corresponding JWT token is issued by the appropriate identity provider. Users and parties without *identity_provider_id* defined are assumed to be using the default identity provider, which is configured statically at the participant node's deployment time.

The Ledger API uses the `iss` claim of a JWT token to match the token to a specific IDP. If there is no match, the default IDP is assumed.

The fields of request messages (and sub-messages) are marked either as `Optional` or `Required`:

1. `Optional` denoting the client may leave the field unset when sending a request.
2. `Required` denoting the client must set the field to a non-default value when sending a request.

An identity provider config resource is described by the `IdentityProviderConfig` message. An identity provider config resource, once it has been created, can be modified. In order to update the properties represented by the `IdentityProviderConfig` message use the `UpdateIdentityProviderConfig` RPC. The only fields that can be modified are those marked as `Modifiable`.

CreateIdentityProviderConfig method, v1/admin

Create a new identity provider configuration. The request will fail if the maximum allowed number of separate configurations is reached.

Request: [CreateIdentityProviderConfigRequest](#)

Response: [CreateIdentityProviderConfigResponse](#)

GetIdentityProviderConfig method, v1/admin

Get the identity provider configuration data by id.

Request: [GetIdentityProviderConfigRequest](#)

Response: [GetIdentityProviderConfigResponse](#)

UpdateIdentityProviderConfig method, v1/admin

Update selected modifiable attribute of an identity provider config resource described by the `IdentityProviderConfig` message.

Request: [UpdateIdentityProviderConfigRequest](#)

Response: [UpdateIdentityProviderConfigResponse](#)

ListIdentityProviderConfigs method, v1/admin

List all existing identity provider configurations.

Request: [ListIdentityProviderConfigsRequest](#)

Response: [ListIdentityProviderConfigsResponse](#)

DeleteIdentityProviderConfig method, v1/admin

Delete an existing identity provider configuration.

Request: [DeleteIdentityProviderConfigRequest](#)

Response: [DeleteIdentityProviderConfigResponse](#)

CreateIdentityProviderConfigRequest message, v1/admin

`identity_provider_config`: [IdentityProviderConfig](#)

Required

CreateIdentityProviderConfigResponse message, v1/admin

`identity_provider_config`: [IdentityProviderConfig](#)

DeleteIdentityProviderConfigRequest message, v1/admin

identity_provider_id: *string*

The identity provider config to delete. Required

DeleteIdentityProviderConfigResponse message, v1/admin

Does not (yet) contain any data.

Message has no fields.

GetIdentityProviderConfigRequest message, v1/admin

identity_provider_id: *string*

Required

GetIdentityProviderConfigResponse message, v1/admin

identity_provider_config: *IdentityProviderConfig*

IdentityProviderConfig message, v1/admin

identity_provider_id: *string*

The identity provider identifier Must be a valid LedgerString (as describe in `value.proto`). Required

is_deactivated: *bool*

When set, the callers using JWT tokens issued by this identity provider are denied all access to the Ledger API. Optional, Modifiable

issuer: *string*

Specifies the issuer of the JWT token. The issuer value is a case sensitive URL using the https scheme that contains scheme, host, and optionally, port number and path components and no query or fragment components. Required Modifiable

jwks_url: *string*

The JWKS (JSON Web Key Set) URL. The Ledger API uses JWKS (JSON Web Keys) from the provided URL to verify that the JWT has been signed with the loaded JWK. Only RS256 (RSA Signature with SHA-256) signing algorithm is supported. Required Modifiable

audience: *string*

Specifies the audience of the JWT token. When set, the callers using JWT tokens issued by this identity provider are allowed to get an access only if the `aud` claim includes the string specified here Optional, Modifiable

ListIdentityProviderConfigsRequest message, v1/admin

Pagination is not required as the resulting data set is small enough to be returned in a single call
Message has no fields.

ListIdentityProviderConfigsResponse message, v1/admin

identity_provider_configs: [IdentityProviderConfig](#) (repeated)

UpdateIdentityProviderConfigRequest message, v1/admin

identity_provider_config: [IdentityProviderConfig](#)

The identity provider config to update. Required, Modifiable

update_mask: [google.protobuf.FieldMask](#)

An update mask specifies how and which properties of the `IdentityProviderConfig` message are to be updated. An update mask consists of a set of update paths. A valid update path points to a field or a subfield relative to the `IdentityProviderConfig` message. A valid update mask must:

1. contain at least one update path,
2. contain only valid update paths.

Fields that can be updated are marked as `Modifiable`. For additional information see the documentation for standard protobuf3's `google.protobuf.FieldMask`. Required

UpdateIdentityProviderConfigResponse message, v1/admin

identity_provider_config: [IdentityProviderConfig](#)

Updated identity provider config

`com/daml/ledger/api/v1/admin/metering_report_service.proto`

12.5.8.5 MeteringReportService, v1/admin

Experimental API to retrieve metering reports.

Metering reports aim to provide the information necessary for billing participant and application operators.

GetMeteringReport method, v1/admin

Retrieve a metering report.

Request: [GetMeteringReportRequest](#)

Response: [GetMeteringReportResponse](#)

GetMeteringReportRequest message, v1/admin

Authorized if and only if the authenticated user is a participant admin.

from: [google.protobuf.Timestamp](#)

The from timestamp (inclusive). Required.

to: [google.protobuf.Timestamp](#)

The to timestamp (exclusive). If not provided, the server will default to its current time.

application_id: [string](#)

If set to a non-empty value, then the report will only be generated for that application. Optional.

GetMeteringReportResponse message, v1/admin

request: [GetMeteringReportRequest](#)

The actual request that was executed.

report_generation_time: [google.protobuf.Timestamp](#)

The time at which the report was computed.

metering_report_json: [google.protobuf.Struct](#)

The metering report json. For a JSON Schema definition of the JSon see: <https://github.com/digital-asset/daml/blob/main/ledger-api/grpc-definitions/metering-report-schema.json>

com/daml/ledger/api/v1/admin/object_meta.proto

ObjectMeta message, v1/admin

Represents metadata corresponding to a participant resource (e.g. a participant user or participant local information about a party).

Based on ObjectMeta meta used in Kubernetes API. See <https://github.com/kubernetes/apimachinery/blob/master/pkg/apis/meta/v1/generated.proto#L640>

resource_version: [string](#)

An opaque, non-empty value, populated by a participant server which represents the internal version of the resource this ObjectMeta message is attached to. The participant server will change it to a unique value each time the corresponding resource is updated. You must not rely on the format of resource version. The participant server might change it without notice. You can obtain the newest resource version value by issuing a read request. You may use it for concurrent change detection

by passing it back unmodified in an update request. The participant server will then compare the passed value with the value maintained by the system to determine if any other updates took place since you had read the resource version. Upon a successful update you are guaranteed that no other update took place during your read-modify-write sequence. However, if another update took place during your read-modify-write sequence then your update will fail with an appropriate error. Concurrent change control is optional. It will be applied only if you include a resource version in an update request. When creating a new instance of a resource you must leave the resource version empty. Its value will be populated by the participant server upon successful resource creation. Optional

annotations: [ObjectMeta.AnnotationsEntry](#) (repeated)

A set of modifiable key-value pairs that can be used to represent arbitrary, client-specific metadata. Constraints:

1. The total size over all keys and values cannot exceed 256kb in UTF-8 encoding.
2. Keys are composed of an optional prefix segment and a required name segment such that:
 - key prefix, when present, must be a valid DNS subdomain with at most 253 characters, followed by a '/' (forward slash) character,
 - name segment must have at most 63 characters that are either alphanumeric ([a-z0-9A-Z]), or a '.' (dot), '-' (dash) or '_' (underscore); and it must start and end with an alphanumeric character.
3. Values can be any non-empty strings.

Keys with empty prefix are reserved for end-users. Properties set by external tools or internally by the participant server must use non-empty key prefixes. Duplicate keys are disallowed by the semantics of the protobuf3 maps. See: <https://developers.google.com/protocol-buffers/docs/proto3#maps> Annotations may be a part of a modifiable resource. Use the resource's update RPC to update its annotations. In order to add a new annotation or update an existing one using an update RPC, provide the desired annotation in the update request. In order to remove an annotation using an update RPC, provide the target annotation's key but set its value to the empty string in the update request. Optional Modifiable

[ObjectMeta.AnnotationsEntry message, v1/admin](#)

key: [string](#)

value: [string](#)

com/daml/ledger/api/v1/admin/package_management_service.proto

12.5.8.6 PackageManagementService, v1/admin

Status: experimental interface, will change before it is deemed production ready

Query the Daml-LF packages supported by the ledger participant and upload DAR files. We use 'backing participant' to refer to this specific participant in the methods of this API.

ListKnownPackages method, v1/admin

Returns the details of all Daml-LF packages known to the backing participant.

Request: [ListKnownPackagesRequest](#)

Response: [ListKnownPackagesResponse](#)

UploadDarFile method, v1/admin

Upload a DAR file to the backing participant. Depending on the ledger implementation this might also make the package available on the whole ledger. This call might not be supported by some ledger implementations. Canton could be an example, where uploading a DAR is not sufficient to render it usable, it must be activated first. This call may:

Succeed, if the package was successfully uploaded, or if the same package was already uploaded before.

Respond with a gRPC error

Request: [UploadDarFileRequest](#)

Response: [UploadDarFileResponse](#)

ValidateDarFile method, v1/admin

Performs the same checks that UploadDarFile call performs, but doesn't persist the DAR and does not make it available for command execution. This call: - Succeeds if the packages contained in the DAR are valid - Respond with a gRPC error if the provided packages are not valid

Request: [ValidateDarFileRequest](#)

Response: [ValidateDarFileResponse](#)

ListKnownPackagesRequest message, v1/admin

Message has no fields.

ListKnownPackagesResponse message, v1/admin

`package_details`: [PackageDetails](#) (repeated)

The details of all Daml-LF packages known to backing participant. Required

PackageDetails message, v1/admin

package_id: *string*

The identity of the Daml-LF package. Must be a valid PackageIdString (as describe in `value.proto`). Required

package_size: *uint64*

Size of the package in bytes. The size of the package is given by the size of the `daml_lf ArchivePayload`. See further details in `daml_lf.proto`. Required

known_since: *google.protobuf.Timestamp*

Indicates since when the package is known to the backing participant. Required

source_description: *string*

Description provided by the backing participant describing where it got the package from. Optional

UploadDarFileRequest message, v1/admin

dar_file: *bytes*

Contains a Daml archive DAR file, which in turn is a jar like zipped container for `daml_lf` archives. See further details in `daml_lf.proto`. Required

submission_id: *string*

Unique submission identifier. Optional, defaults to a random identifier.

UploadDarFileResponse message, v1/admin

An empty message that is received when the upload operation succeeded.

Message has no fields.

ValidateDarFileRequest message, v1/admin

dar_file: *bytes*

Contains a Daml archive DAR file, which in turn is a jar like zipped container for `daml_lf` archives. See further details in `daml_lf.proto`. Required

submission_id: *string*

Unique submission identifier. Optional, defaults to a random identifier.

ValidateDarFileResponse message, v1/admin

Message has no fields.

`com/daml/ledger/api/v1/admin/participant_pruning_service.proto`

12.5.8.7 ParticipantPruningService, v1/admin

Prunes/truncates the oldest transactions from the participant (the participant Ledger Api Server plus any other participant-local state) by removing a portion of the ledger in such a way that the set of future, allowed commands are not affected.

This enables:

1. keeping the inactive portion of the ledger to a manageable size and
2. removing inactive state to honor the right to be forgotten.

Prune method, v1/admin

Prune the ledger specifying the offset before and at which ledger transactions should be removed. Only returns when the potentially long-running prune request ends successfully or with an error.

Request: [PruneRequest](#)

Response: [PruneResponse](#)

PruneRequest message, v1/admin

`prune_up_to`: [string](#)

Inclusive offset up to which the ledger is to be pruned. By default the following data is pruned:

1. All normal and divulged contracts that have been archived before `prune_up_to`.
2. All transaction events and completions before `prune_up_to`

`submission_id`: [string](#)

Unique submission identifier. Optional, defaults to a random identifier, used for logging.

`prune_all_divulged_contracts`: [bool](#)

Prune all immediately and retroactively divulged contracts created before `prune_up_to` independent of whether they were archived before `prune_up_to`. Useful to avoid leaking storage on participant nodes that can see a divulged contract but not its archival.

Application developers SHOULD write their Daml applications such that they do not rely on divulged contracts; i.e., no warnings from using divulged contracts as inputs to transactions are emitted.

Participant node operators SHOULD set the `prune_all_divulged_contracts` flag to avoid leaking storage due to accumulating unarchived divulged contracts PROVIDED that:

1. no application using this participant node relies on divulgence OR
2. divulged contracts on which applications rely have been re-divulged after the `prune_up_to` offset.

PruneResponse message, v1/admin

Empty for now, but may contain fields in the future

Message has no fields.

com/daml/ledger/api/v1/admin/party_management_service.proto

12.5.8.8 PartyManagementService, v1/admin

This service allows inspecting the party management state of the ledger known to the participant and managing the participant-local party metadata.

The authorization rules for its RPCs are specified on the `<RpcName>Request` messages as boolean expressions over these facts:

1. `HasRight(r)` denoting whether the authenticated user has right `r` and
2. `IsAuthenticatedIdentityProviderAdmin(idp)` denoting whether `idp` is equal to the `identity_provider_id` of the authenticated user and the user has an `IdentityProviderAdmin` right.

If `identity_provider_id` is set to an empty string, then it's effectively set to the value of access token's 'iss' field if that is provided. If `identity_provider_id` remains an empty string, the default identity provider will be assumed.

The fields of request messages (and sub-messages) are marked either as `Optional` or `Required`:

1. `Optional` denoting the client may leave the field unset when sending a request.
2. `Required` denoting the client must set the field to a non-default value when sending a request.

A party details resource is described by the `PartyDetails` message. A party details resource, once it has been created, can be modified using the `UpdatePartyDetails` RPC. The only fields that can be modified are those marked as `Modifiable`.

GetParticipantId method, v1/admin

Return the identifier of the participant. All horizontally scaled replicas should return the same id.
daml-on-kv-ledger: returns an identifier supplied on command line at launch time
canton: returns globally unique identifier of the participant

Request: [GetParticipantIdRequest](#)

Response: [GetParticipantIdResponse](#)

GetParties method, v1/admin

Get the party details of the given parties. Only known parties will be returned in the list.

Request: [GetPartiesRequest](#)

Response: [GetPartiesResponse](#)

ListKnownParties method, v1/admin

List the parties known by the participant. The list returned contains parties whose ledger access is facilitated by the participant and the ones maintained elsewhere.

Request: [ListKnownPartiesRequest](#)

Response: [ListKnownPartiesResponse](#)

AllocateParty method, v1/admin

Allocates a new party on a ledger and adds it to the set managed by the participant. Caller specifies a party identifier suggestion, the actual identifier allocated might be different and is implementation specific. Caller can specify party metadata that is stored locally on the participant. This call may:

Succeed, in which case the actual allocated identifier is visible in the response.

Respond with a gRPC error

daml-on-kv-ledger: suggestion's uniqueness is checked by the validators in the consensus layer and call rejected if the identifier is already present. canton: completely different globally unique identifier is allocated. Behind the scenes calls to an internal protocol are made. As that protocol is richer than the surface protocol, the arguments take implicit values The party identifier suggestion must be a valid party name. Party names are required to be non-empty US-ASCII strings built from letters, digits, space, colon, minus and underscore limited to 255 chars

Request: [AllocatePartyRequest](#)

Response: [AllocatePartyResponse](#)

UpdatePartyDetails method, v1/admin

Update selected modifiable participant-local attributes of a party details resource. Can update the participant's local information for local parties.

Request: [UpdatePartyDetailsRequest](#)

Response: [UpdatePartyDetailsResponse](#)

UpdatePartyIdentityProviderId method, v1/admin

Update the assignment of a party from one IDP to another.

Request: [UpdatePartyIdentityProviderRequest](#)

Response: [UpdatePartyIdentityProviderResponse](#)

AllocatePartyRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin) OR IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

`party_id_hint`: [string](#)

A hint to the participant which party ID to allocate. It can be ignored. Must be a valid `PartyIdString` (as described in `value.proto`). Optional

`display_name`: [string](#)

Human-readable name of the party to be added to the participant. It doesn't have to be unique. Use of this field is discouraged. Use `local_metadata` instead. Optional

`local_metadata`: [ObjectMeta](#)

Participant-local metadata to be stored in the `PartyDetails` of this newly allocated party. Optional

`identity_provider_id`: [string](#)

The id of the `Identity Provider` Optional, if not set, assume the party is managed by the default identity provider or party is not hosted by the participant.

AllocatePartyResponse message, v1/admin

`party_details`: [PartyDetails](#)

GetParticipantIdRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin)`

Message has no fields.

GetParticipantIdResponse message, v1/admin

`participant_id`: [string](#)

Identifier of the participant, which SHOULD be globally unique. Must be a valid `LedgerString` (as describe in `value.proto`).

GetPartiesRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin) OR IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

`parties`: [string](#) (repeated)

The stable, unique identifier of the Daml parties. Must be valid PartyIdStrings (as described in `value.proto`). Required

`identity_provider_id`: [string](#)

The id of the Identity Provider whose parties should be retrieved. Optional, if not set, assume the party is managed by the default identity provider or party is not hosted by the participant.

GetPartiesResponse message, v1/admin

`party_details`: [PartyDetails](#) (repeated)

The details of the requested Daml parties by the participant, if known. The party details may not be in the same order as requested. Required

ListKnownPartiesRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin) OR IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

`page_token`: [string](#)

Pagination token to determine the specific page to fetch. Using the token guarantees that parties on a subsequent page are all lexically greater than the last party on a previous page. Server does not store intermediate results between calls chained by a series of page tokens. As a consequence, if new parties are being added and a page is requested twice using the same token, more parties can be returned on the second call. Leave empty to fetch the first page. Optional

`page_size`: [int32](#)

Maximum number of results to be returned by the server. The server will return no more than that many results, but it might return fewer. If the `page_size` is 0, the server will decide the number of results to be returned. If the `page_size` exceeds the maximum supported by the server, an error will be returned. To obtain the server's maximum consult the `PartyManagementFeature` descriptor available in the `VersionService`. Optional

`identity_provider_id`: [string](#)

The id of the Identity Provider whose parties should be retrieved. Optional, if not set, assume the party is managed by the default identity provider or party is not hosted by the participant.

ListKnownPartiesResponse message, v1/admin

party_details: [PartyDetails](#) (repeated)

The details of all Daml parties known by the participant. Required

next_page_token: [string](#)

Pagination token to retrieve the next page. Empty, if there are no further results.

PartyDetails message, v1/admin

party: [string](#)

The stable unique identifier of a Daml party. Must be a valid PartyIdString (as described in `value.proto`). Required

display_name: [string](#)

Human readable name associated with the party at allocation time. Caution, it might not be unique. Use of this field is discouraged. Use the `local_metadata` field instead. Optional

is_local: [bool](#)

true if party is hosted by the participant and the party shares the same identity provider as the user issuing the request. Optional

local_metadata: [ObjectMeta](#)

Participant-local metadata of this party. Optional, Modifiable

identity_provider_id: [string](#)

The id of the Identity Provider Optional, if not set, there could be 3 options:

1. the party is managed by the default identity provider.
2. party is not hosted by the participant.
3. party is hosted by the participant, but is outside of the user's identity provider.

UpdatePartyDetailsRequest message, v1/admin

Required authorization: `HasRight (ParticipantAdmin) OR IsAuthenticatedIdentityProviderAdmin`
identity_provider_id

party_details: [PartyDetails](#)

Party to be updated Required, Modifiable

update_mask: [google.protobuf.FieldMask](#)

An update mask specifies how and which properties of the `PartyDetails` message are to be updated. An update mask consists of a set of update paths. A valid update path points to a field or a subfield relative to the `PartyDetails` message. A valid update mask must:

1. contain at least one update path,
2. contain only valid update paths.

Fields that can be updated are marked as `Modifiable`. An update path can also point to non-`Modifiable` fields such as `'party'` and `'local_metadata.resource_version'` because they are used:

1. to identify the party details resource subject to the update,
2. for concurrent change control.

An update path can also point to non-`Modifiable` fields such as `'is_local'` and `'display_name'` as long as the values provided in the update request match the server values. Examples of update paths: `'local_metadata.annotations'`, `'local_metadata'`. For additional information see the documentation for standard protobuf3's `google.protobuf.FieldMask`. For similar Ledger API see `com.daml.ledger.api.v1.admin.UpdateUserRequest`. **Required**

UpdatePartyDetailsResponse message, v1/admin

`party_details`: [PartyDetails](#)

Updated party details

UpdatePartyIdentityProviderRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin)`

`party`: [string](#)

Party to update

`source_identity_provider_id`: [string](#)

Current identity provider id of the party

`target_identity_provider_id`: [string](#)

Target identity provider id of the party

UpdatePartyIdentityProviderResponse message, v1/admin

Message has no fields.

`com/daml/ledger/api/v1/admin/user_management_service.proto`

12.5.8.9 UserManagementService, v1/admin

Service to manage users and their rights for interacting with the Ledger API served by a participant node.

The authorization rules for its RPCs are specified on the `<RpcName>Request` messages as boolean expressions over these facts:

1. `HasRight(r)` denoting whether the authenticated user has right `r` and
2. `IsAuthenticatedUser(uid)` denoting whether `uid` is the empty string or equal to the id of the authenticated user.

3. `IsAuthenticatedIdentityProviderAdmin(idp)` denoting whether `idp` is equal to the `identity_provider_id` of the authenticated user and the user has an `IdentityProviderAdmin` right.

If `user_id` is set to the empty string (the default), then the data for the authenticated user will be retrieved. If `identity_provider_id` is set to an empty string, then it's effectively set to the value of access token's 'iss' field if that is provided. If `identity_provider_id` remains an empty string, the default identity provider will be assumed.

The fields of request messages (and sub-messages) are marked either as `Optional` or `Required`:

1. `Optional` denoting the client may leave the field unset when sending a request.
2. `Required` denoting the client must set the field to a non-default value when sending a request.

A user resource consists of:

1. a set of properties represented by the `User` message,
2. a set of user rights, where each right is represented by the `Right` message.

A user resource, once it has been created, can be modified. In order to update the properties represented by the `User` message use the `UpdateUser` RPC. The only fields that can be modified are those marked as `Modifiable`. In order to grant or revoke user rights use `GrantRights` and `RevokeRights` RPCs.

CreateUser method, `v1/admin`

Create a new user.

Request: [CreateUserRequest](#)

Response: [CreateUserResponse](#)

GetUser method, `v1/admin`

Get the user data of a specific user or the authenticated user.

Request: [GetUserRequest](#)

Response: [GetUserResponse](#)

UpdateUser method, `v1/admin`

Update selected modifiable attribute of a user resource described by the `User` message.

Request: [UpdateUserRequest](#)

Response: [UpdateUserResponse](#)

DeleteUser method, v1/admin

Delete an existing user and all its rights.

Request: [DeleteUserRequest](#)

Response: [DeleteUserResponse](#)

ListUsers method, v1/admin

List all existing users.

Request: [ListUsersRequest](#)

Response: [ListUsersResponse](#)

GrantUserRights method, v1/admin

Grant rights to a user. Granting rights does not affect the resource version of the corresponding user.

Request: [GrantUserRightsRequest](#)

Response: [GrantUserRightsResponse](#)

RevokeUserRights method, v1/admin

Revoke rights from a user. Revoking rights does not affect the resource version of the corresponding user.

Request: [RevokeUserRightsRequest](#)

Response: [RevokeUserRightsResponse](#)

ListUserRights method, v1/admin

List the set of all rights granted to a user.

Request: [ListUserRightsRequest](#)

Response: [ListUserRightsResponse](#)

UpdateUserIdentityProviderId method, v1/admin

Update the assignment of a user from one IDP to another.

Request: [UpdateUserIdentityProviderRequest](#)

Response: [UpdateUserIdentityProviderResponse](#)

CreateUserRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin)` OR `IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

`user`: [User](#)

The user to create. Required

`rights`: [Right](#) (repeated)

The rights to be assigned to the user upon creation, which SHOULD include appropriate rights for the `user.primary_party`. Optional

CreateUserResponse message, v1/admin

`user`: [User](#)

Created user.

DeleteUserRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin)` OR `IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

`user_id`: [string](#)

The user to delete. Required

`identity_provider_id`: [string](#)

The id of the Identity Provider Optional, if not set, assume the user is managed by the default identity provider.

DeleteUserResponse message, v1/admin

Does not (yet) contain any data.

Message has no fields.

GetUserRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin)` OR `IsAuthenticatedIdentityProviderAdmin(identity_provider_id)` OR `IsAuthenticatedUser(user_id)`

`user_id`: [string](#)

The user whose data to retrieve. If set to empty string (the default), then the data for the authenticated user will be retrieved. Optional

`identity_provider_id`: [string](#)

The id of the Identity Provider Optional, if not set, assume the user is managed by the default identity provider.

GetUserResponse message, v1/admin

user : [User](#)

Retrieved user.

GrantUserRightsRequest message, v1/admin

Add the rights to the set of rights granted to the user.

Required authorization: `HasRight(ParticipantAdmin)` OR `IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

user_id : [string](#)

The user to whom to grant rights. Required

rights : [Right](#) (repeated)

The rights to grant. Optional

identity_provider_id : [string](#)

The id of the `Identity Provider` Optional, if not set, assume the user is managed by the default identity provider.

GrantUserRightsResponse message, v1/admin

newly_granted_rights : [Right](#) (repeated)

The rights that were newly granted by the request.

ListUserRightsRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin)` OR `IsAuthenticatedIdentityProviderAdmin(identity_provider_id)` OR `IsAuthenticatedUser(user_id)`

user_id : [string](#)

The user for which to list the rights. If set to empty string (the default), then the rights for the authenticated user will be listed. Required

identity_provider_id : [string](#)

The id of the `Identity Provider` Optional, if not set, assume the user is managed by the default identity provider.

ListUserRightsResponse message, v1/admin

rights : [Right](#) (repeated)

All rights of the user.

ListUsersRequest message, v1/admin

Required authorization: `HasRight(ParticipantAdmin)` OR `IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

page_token : [string](#)

Pagination token to determine the specific page to fetch. Leave empty to fetch the first page. Optional

page_size : [int32](#)

Maximum number of results to be returned by the server. The server will return no more than that many results, but it might return fewer. If 0, the server will decide the number of results to be returned. Optional

identity_provider_id : [string](#)

The id of the Identity Provider Optional, if not set, assume the user is managed by the default identity provider.

ListUsersResponse message, v1/admin

users : [User](#) (repeated)

A subset of users of the participant node that fit into this page.

next_page_token : [string](#)

Pagination token to retrieve the next page. Empty, if there are no further results.

RevokeUserRightsRequest message, v1/admin

Remove the rights from the set of rights granted to the user.

Required authorization: `HasRight(ParticipantAdmin)` OR `IsAuthenticatedIdentityProviderAdmin(identity_provider_id)`

user_id : [string](#)

The user from whom to revoke rights. Required

rights : [Right](#) (repeated)

The rights to revoke. Optional

identity_provider_id : [string](#)

The id of the Identity Provider Optional, if not set, assume the user is managed by the default identity provider.

RevokeUserRightsResponse message, v1/admin

newly_revoked_rights: [Right](#) (repeated)

The rights that were actually revoked by the request.

Right message, v1/admin

A right granted to a user.

oneof kind.participant_admin: [Right.ParticipantAdmin](#)

The user can administer the participant node.

oneof kind.can_act_as: [Right.CanActAs](#)

The user can act as a specific party.

oneof kind.can_read_as: [Right.CanReadAs](#)

The user can read ledger data visible to a specific party.

oneof kind.identity_provider_admin: [Right.IdentityProviderAdmin](#)

The user can administer users and parties assigned to the same identity provider as the one of the user.

Right.CanActAs message, v1/admin

party: [string](#)

The right to authorize commands for this party.

Right.CanReadAs message, v1/admin

party: [string](#)

The right to read ledger data visible to this party.

Right.IdentityProviderAdmin message, v1/admin

The right to administer the identity provider that the user is assigned to. It means, being able to manage users and parties that are also assigned to the same identity provider.

Message has no fields.

Right.ParticipantAdmin message, v1/admin

The right to administer the participant node.

Message has no fields.

UpdateUserIdentityProviderRequest message, v1/admin

Required authorization: HasRight (ParticipantAdmin)

user_id: [string](#)

User to update

source_identity_provider_id: [string](#)

Current identity provider id of the user

target_identity_provider_id: [string](#)

Target identity provider id of the user

UpdateUserIdentityProviderResponse message, v1/admin

Message has no fields.

UpdateUserRequest message, v1/admin

Required authorization: HasRight (ParticipantAdmin) OR IsAuthenticatedIdentityProviderAdmin (identity_provider_id)

user: [User](#)

The user to update. Required, Modifiable

update_mask: [google.protobuf.FieldMask](#)

An update mask specifies how and which properties of the `User` message are to be updated. An update mask consists of a set of update paths. A valid update path points to a field or a subfield relative to the `User` message. A valid update mask must:

1. contain at least one update path,
2. contain only valid update paths.

Fields that can be updated are marked as `Modifiable`. An update path can also point to a non-`Modifiable` fields such as 'id' and 'metadata.resource_version' because they are used:

1. to identify the user resource subject to the update,
2. for concurrent change control.

Examples of valid update paths: 'primary_party', 'metadata', 'metadata.annotations'. For additional information see the documentation for standard protobuf3's `google.protobuf.FieldMask`. For similar Ledger API see `com.daml.ledger.api.v1.admin.UpdatePartyDetailsRequest`. Required

UpdateUserResponse message, v1/admin

user: [User](#)

Updated user

User message, v1/admin

Users are used to dynamically manage the rights given to Daml applications. They are stored and managed per participant node.

Read the [Authorization documentation](#) to learn more.

id: [string](#)

The user identifier, which must be a non-empty string of at most 128 characters that are either alphanumeric ASCII characters or one of the symbols `@^$.!`~#+~_|`: . Required

primary_party: [string](#)

The primary party as which this user reads and acts by default on the ledger *provided* it has the corresponding `CanReadAs(primary_party)` or `CanActAs(primary_party)` rights. Ledger API clients SHOULD set this field to a non-empty value for all users to enable the users to act on the ledger using their own Daml party. Users for participant administrators MAY have an associated primary party. Optional, Modifiable

is_deactivated: [bool](#)

When set, then the user is denied all access to the Ledger API. Otherwise, the user has access to the Ledger API as per the user's rights. Optional, Modifiable

metadata: [ObjectMeta](#)

The metadata of this user. Note that the `metadata.resource_version` tracks changes to the properties described by the `User` message and not the user's rights. Optional, Modifiable

identity_provider_id: [string](#)

The id of the identity provider configured by `Identity Provider Config` Optional, if not set, assume the user is managed by the default identity provider.

`com/daml/ledger/api/v1/command_completion_service.proto`

12.5.8.10 CommandCompletionService, v1

Allows clients to observe the status of their submissions. Commands may be submitted via the Command Submission Service. The on-ledger effects of their submissions are disclosed by the Transaction Service.

Commands may fail in 2 distinct manners:

1. Failure communicated synchronously in the gRPC error of the submission.
2. Failure communicated asynchronously in a Completion, see `completion.proto`.

Note that not only successfully submitted commands MAY produce a completion event. For example, the participant MAY choose to produce a completion event for a rejection of a duplicate command.

Clients that do not receive a successful completion about their submission MUST NOT assume that it was successful. Clients SHOULD subscribe to the CompletionStream before starting to submit commands to prevent race conditions.

CompletionStream method, v1

Subscribe to command completion events.

Request: [CompletionStreamRequest](#)

Response: [CompletionStreamResponse](#)

CompletionEnd method, v1

Returns the offset after the latest completion.

Request: [CompletionEndRequest](#)

Response: [CompletionEndResponse](#)

Checkpoint message, v1

Checkpoints may be used to:

- detect time out of commands.

- provide an offset which can be used to restart consumption.

record_time: [google.protobuf.Timestamp](#)

All commands with a maximum record time below this value MUST be considered lost if their completion has not arrived before this checkpoint. Required

offset: [LedgerOffset](#)

May be used in a subsequent CompletionStreamRequest to resume the consumption of this stream at a later time. Required

CompletionEndRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

CompletionEndResponse message, v1

offset: [LedgerOffset](#)

This offset can be used in a CompletionStreamRequest message. Required

CompletionStreamRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger id reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

application_id: [string](#)

Only completions of commands submitted with the same application_id will be visible in the stream. Must be a valid ApplicationIdString (as described in `value.proto`). Required unless authentication is used with a user token or a custom token specifying an application-id. In that case, the token's user-id, respectively application-id, will be used for the request's application_id.

parties: [string](#) (repeated)

Non-empty list of parties whose data should be included. Only completions of commands for which at least one of the `act_as` parties is in the given set of parties will be visible in the stream. Must be a valid PartyIdString (as described in `value.proto`). Required

offset: [LedgerOffset](#)

This field indicates the minimum offset for completions. This can be used to resume an earlier completion stream. This offset is exclusive: the response will only contain commands whose offset is strictly greater than this. Optional, if not set the ledger uses the current ledger end offset instead.

CompletionStreamResponse message, v1

checkpoint: [Checkpoint](#)

This checkpoint may be used to restart consumption. The checkpoint is after any completions in this response. Optional

completions: [Completion](#) (repeated)

If set, one or more completions.

`com/daml/ledger/api/v1/command_service.proto`

12.5.8.11 `CommandService`, v1

Command Service is able to correlate submitted commands with completion data, identify timeouts, and return contextual information with each tracking result. This supports the implementation of stateless clients.

Note that submitted commands generally produce completion events as well, even in case a command gets rejected. For example, the participant MAY choose to produce a completion event for a rejection of a duplicate command.

`SubmitAndWait` method, v1

Submits a single composite command and waits for its result. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [.google.protobuf.Empty](#)

`SubmitAndWaitForTransactionId` method, v1

Submits a single composite command, waits for its result, and returns the transaction id. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [SubmitAndWaitForTransactionIdResponse](#)

`SubmitAndWaitForTransaction` method, v1

Submits a single composite command, waits for its result, and returns the transaction. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [SubmitAndWaitForTransactionResponse](#)

`SubmitAndWaitForTransactionTree` method, v1

Submits a single composite command, waits for its result, and returns the transaction tree. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [SubmitAndWaitForTransactionTreeResponse](#)

SubmitAndWaitForTransactionIdResponse message, v1

transaction_id: [string](#)

The id of the transaction that resulted from the submitted command. Must be a valid LedgerString (as described in `value.proto`). Required

completion_offset: [string](#)

The format of this field is described in `ledger_offset.proto`. Optional

SubmitAndWaitForTransactionResponse message, v1

transaction: [Transaction](#)

The flat transaction that resulted from the submitted command. Required

completion_offset: [string](#)

The format of this field is described in `ledger_offset.proto`. Optional

SubmitAndWaitForTransactionTreeResponse message, v1

transaction: [TransactionTree](#)

The transaction tree that resulted from the submitted command. Required

completion_offset: [string](#)

The format of this field is described in `ledger_offset.proto`. Optional

SubmitAndWaitRequest message, v1

These commands are atomic, and will become transactions.

commands: [Commands](#)

The commands to be submitted. Required

`com/daml/ledger/api/v1/command_submission_service.proto`

12.5.8.12 CommandSubmissionService, v1

Allows clients to attempt advancing the ledger's state by submitting commands. The final states of their submissions are disclosed by the Command Completion Service. The on-ledger effects of their submissions are disclosed by the Transaction Service.

Commands may fail in 2 distinct manners:

1. Failure communicated synchronously in the gRPC error of the submission.
2. Failure communicated asynchronously in a Completion, see `completion.proto`.

Note that not only successfully submitted commands MAY produce a completion event. For example, the participant MAY choose to produce a completion event for a rejection of a duplicate command.

Clients that do not receive a successful completion about their submission MUST NOT assume that it was successful. Clients SHOULD subscribe to the CompletionStream before starting to submit commands to prevent race conditions.

Submit method, v1

Submit a single composite command.

Request: [SubmitRequest](#)

Response: [.google.protobuf.Empty](#)

SubmitRequest message, v1

The submitted commands will be processed atomically in a single transaction. Moreover, each Command in commands will be executed in the order specified by the request.

commands : [Commands](#)

The commands to be submitted in a single transaction. Required

com/daml/ledger/api/v1/commands.proto

Command message, v1

A command can either create a new contract or exercise a choice on an existing contract.

oneof command.create : [CreateCommand](#)

oneof command.exercise : [ExerciseCommand](#)

oneof command.exerciseByKey : [ExerciseByKeyCommand](#)

oneof command.createAndExercise : [CreateAndExerciseCommand](#)

Commands message, v1

A composite command that groups multiple commands together.

ledger_id : [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid LedgerString (as described in [value.proto](#)). Optional

workflow_id : [string](#)

Identifier of the on-ledger workflow that this command is a part of. Must be a valid LedgerString (as described in [value.proto](#)). Optional

application_id : [string](#)

Uniquely identifies the application or participant user that issued the command. Must be a valid `ApplicationIdString` (as described in `value.proto`). Required unless authentication is used with a user token or a custom token specifying an application-id. In that case, the token's user-id, respectively application-id, will be used for the request's `application_id`.

`command_id`: [string](#)

Uniquely identifies the command. The triple (`application_id`, `party + act_as`, `command_id`) constitutes the change ID for the intended ledger change, where `party + act_as` is interpreted as a set of party names. The change ID can be used for matching the intended ledger changes with all their completions. Must be a valid `LedgerString` (as described in `value.proto`). Required

`party`: [string](#)

Party on whose behalf the command should be executed. If ledger API authorization is enabled, then the authorization metadata must authorize the sender of the request to act on behalf of the given party. Must be a valid `PartyIdString` (as described in `value.proto`). Deprecated in favor of the `act_as` field. If both are set, then the effective list of parties on whose behalf the command should be executed is the union of all parties listed in `party` and `act_as`. Optional

`commands`: [Command](#) (repeated)

Individual elements of this atomic command. Must be non-empty. Required

`oneof deduplication_period.deduplication_time`: [google.protobuf.Duration](#)

Specifies the length of the deduplication period. Same semantics apply as for `deduplication_duration`. Must be non-negative. Must not exceed the maximum deduplication time (see `ledger_configuration_service.proto`).

`oneof deduplication_period.deduplication_duration`: [google.protobuf.Duration](#)

Specifies the length of the deduplication period. It is interpreted relative to the local clock at some point during the submission's processing. Must be non-negative. Must not exceed the maximum deduplication time (see `ledger_configuration_service.proto`).

`oneof deduplication_period.deduplication_offset`: [string](#)

Specifies the start of the deduplication period by a completion stream offset (exclusive). Must be a valid `LedgerString` (as described in `ledger_offset.proto`).

`min_ledger_time_abs`: [google.protobuf.Timestamp](#)

Lower bound for the ledger time assigned to the resulting transaction. Note: The ledger time of a transaction is assigned as part of command interpretation. Use this property if you expect that command interpretation will take a considerable amount of time, such that by the time the resulting transaction is sequenced, its assigned ledger time is not valid anymore. Must not be set at the same time as `min_ledger_time_rel`. Optional

`min_ledger_time_rel`: [google.protobuf.Duration](#)

Same as `min_ledger_time_abs`, but specified as a duration, starting from the time the command is received by the server. Must not be set at the same time as `min_ledger_time_abs`. Optional

`act_as`: [string](#) (repeated)

Set of parties on whose behalf the command should be executed. If ledger API authorization is enabled, then the authorization metadata must authorize the sender of the request to act on behalf of each of the given parties. This field supersedes the `party` field. The effective set of parties on whose behalf the command should be executed is the union of all parties listed in `party` and `act_as`, which

must be non-empty. Each element must be a valid `PartyIdString` (as described in `value.proto`).
Optional

`read_as`: [string](#) (repeated)

Set of parties on whose behalf (in addition to all parties listed in `act_as`) contracts can be retrieved. This affects Daml operations such as `fetch`, `fetchByKey`, `lookupByKey`, `exercise`, and `exerciseByKey`. Note: A participant node of a Daml network can host multiple parties. Each contract present on the participant node is only visible to a subset of these parties. A command can only use contracts that are visible to at least one of the parties in `act_as` or `read_as`. This visibility check is independent from the Daml authorization rules for fetch operations. If ledger API authorization is enabled, then the authorization metadata must authorize the sender of the request to read contract data on behalf of each of the given parties. Optional

`submission_id`: [string](#)

A unique identifier to distinguish completions for different submissions with the same change ID. Typically a random UUID. Applications are expected to use a different UUID for each retry of a submission with the same change ID. Must be a valid `LedgerString` (as described in `value.proto`).

If omitted, the participant or the committer may set a value of their choice. Optional

`disclosed_contracts`: [DisclosedContract](#) (repeated)

Additional contracts used to resolve contract & contract key lookups. Optional

`package_id_selection_preference`: [string](#) (repeated)

The package-id selection preference of the client for resolving package names and interface instances in command submission and interpretation

`prefetch_contract_keys`: [PrefetchContractKey](#) (repeated)

Fetches the contract keys into the caches to speed up the command processing. Should only contain contract keys that are expected to be resolved during interpretation of the commands. Keys of disclosed contracts do not need prefetching.

Optional

CreateAndExerciseCommand message, v1

Create a contract and exercise a choice on it in the same transaction.

`template_id`: [Identifier](#)

The template of the contract the client wants to create. Both package-name and package-id reference identifier formats for the template-id are supported.

Required

`create_arguments`: [Record](#)

The arguments required for creating a contract from this template. Required

`choice`: [string](#)

The name of the choice the client wants to exercise. Must be a valid `NameString` (as described in `value.proto`). Required

`choice_argument`: [Value](#)

The argument for this choice. Required

CreateCommand message, v1

Create a new contract instance based on a template.

template_id: *Identifier*

The template of contract the client wants to create. Both package-name and package-id reference identifier formats for the template-id are supported.

Required

create_arguments: *Record*

The arguments required for creating a contract from this template. Required

DisclosedContract message, v1

An additional contract that is used to resolve contract & contract key lookups.

template_id: *Identifier*

The template id of the contract. The identifier uses the package-id reference format.

Required

contract_id: *string*

The contract id Required

created_event_blob: *bytes*

Opaque byte string containing the complete payload required by the Daml engine to reconstruct a contract not known to the receiving participant. Required

ExerciseByKeyCommand message, v1

Exercise a choice on an existing contract specified by its key.

template_id: *Identifier*

The template of contract the client wants to exercise. Both package-name and package-id reference identifier formats for the template-id are supported.

Required

contract_key: *Value*

The key of the contract the client wants to exercise upon. Required

choice: *string*

The name of the choice the client wants to exercise. Must be a valid NameString (as described in `value.proto`) Required

choice_argument: *Value*

The argument for this choice. Required

ExerciseCommand message, v1

Exercise a choice on an existing contract.

template_id: [Identifier](#)

The template of contract the client wants to exercise. Both package-name and package-id reference identifier formats for the template-id are supported.

Required

contract_id: [string](#)

The ID of the contract the client wants to exercise upon. Must be a valid LedgerString (as described in `value.proto`). Required

choice: [string](#)

The name of the choice the client wants to exercise. Must be a valid NameString (as described in `value.proto`) Required

choice_argument: [Value](#)

The argument for this choice. Required

PrefetchContractKey message, v1

Preload contracts

template_id: [Identifier](#)

The template of contract the client wants to prefetch. Both package-name and package-id reference identifier formats for the template-id are supported.

Required

contract_key: [Value](#)

The key of the contract the client wants to prefetch. Required

`com/daml/ledger/api/v1/completion.proto`

Completion message, v1

A completion represents the status of a submitted command on the ledger: it can be successful or failed.

command_id: [string](#)

The ID of the succeeded or failed command. Must be a valid LedgerString (as described in `value.proto`). Required

status: [google.rpc.Status](#)

Identifies the exact type of the error. It uses the same format of conveying error details as it is used for the RPC responses of the APIs. Optional

transaction_id: [string](#)

The `transaction_id` of the transaction that resulted from the command with `command_id`. Only set for successfully executed commands. Must be a valid `LedgerString` (as described in `value.proto`). Optional

`application_id`: [string](#)

The application-id or user-id that was used for the submission, as described in `commands.proto`. Must be a valid `ApplicationIdString` (as described in `value.proto`). Optional for historic completions where this data is not available.

`act_as`: [string](#) (repeated)

The set of parties on whose behalf the commands were executed. Contains the union of `party` and `act_as` from `commands.proto`. The order of the parties need not be the same as in the submission. Each element must be a valid `PartyIdString` (as described in `value.proto`). Optional for historic completions where this data is not available.

`submission_id`: [string](#)

The submission ID this completion refers to, as described in `commands.proto`. Must be a valid `LedgerString` (as described in `value.proto`). Optional

`oneof deduplication_period.deduplication_offset`: [string](#)

Specifies the start of the deduplication period by a completion stream offset (exclusive).

Must be a valid `LedgerString` (as described in `value.proto`).

`oneof deduplication_period.deduplication_duration`: [google.protobuf.Duration](#)

Specifies the length of the deduplication period. It is measured in record time of completions.

Must be non-negative.

`trace_context`: [TraceContext](#)

Optional; ledger api trace context

The trace context transported in this message corresponds to the trace context supplied by the client application in a HTTP2 header of the original command submission. We typically use a header to transfer this type of information. Here we use message body, because it is used in gRPC streams which do not support per message headers. This field will be populated with the trace context contained in the original submission. If that was not provided, a unique ledger-api-server generated trace context will be used instead.

`com/daml/ledger/api/v1/contract_metadata.proto`

[ContractMetadata message, v1](#)

Contract-related metadata used in `DisclosedContract` (that can be included in command submission) or forwarded as part of the `CreatedEvent` in Active Contract Set or Transaction streams.

`created_at`: [google.protobuf.Timestamp](#)

Ledger effective time of the transaction that created the contract. Required

`contract_key_hash`: [bytes](#)

Hash of the contract key if defined. Optional

`driver_metadata`: [bytes](#)

Driver-specific metadata. This is opaque and cannot be decoded. Optional

`com/daml/ledger/api/v1/event.proto`

ArchivedEvent message, v1

Records that a contract has been archived, and choices may no longer be exercised on it.

`event_id`: [string](#)

The ID of this particular event. Must be a valid LedgerString (as described in `value.proto`). Required

`contract_id`: [string](#)

The ID of the archived contract. Must be a valid LedgerString (as described in `value.proto`). Required

`template_id`: [Identifier](#)

The template of the archived contract. The identifier uses the package-id reference format.

Required

`witness_parties`: [string](#) (repeated)

The parties that are notified of this event. For an `ArchivedEvent`, these are the intersection of the stakeholders of the contract in question and the parties specified in the `TransactionFilter`. The stakeholders are the union of the signatories and the observers of the contract. Each one of its elements must be a valid `PartyIdString` (as described in `value.proto`). Required

`package_name`: [google.protobuf.StringValue](#)

The package name of the archived contract. Optional

CreatedEvent message, v1

Records that a contract has been created, and choices may now be exercised on it.

`event_id`: [string](#)

The ID of this particular event. Must be a valid LedgerString (as described in `value.proto`). Required

`contract_id`: [string](#)

The ID of the created contract. Must be a valid LedgerString (as described in `value.proto`). Required

`template_id`: [Identifier](#)

The template of the created contract. The identifier uses the package-id reference format.

Required

`package_name`: [google.protobuf.StringValue](#)

The package name of the created contract. Optional

`contract_key`: [Value](#)

The key of the created contract. This will be set if and only if `create_arguments` is set and `template_id` defines a contract key. Optional

`create_arguments`: [Record](#)

The arguments that have been used to create the contract. Set either:

- if there was a party, which is in the `witness_parties` of this event, and for which an `InclusiveFilters` exists with the `template_id` of this event among the `template_ids`,
- or if there was a party, which is in the `witness_parties` of this event, and for which a wildcard filter exists (`Filters` without `InclusiveFilters`, or with an `InclusiveFilters` with empty `template_ids` and empty `interface_filters`).

Optional

`created_event_blob`: [bytes](#)

Opaque representation of contract create event payload intended for forwarding to an API server as a contract disclosed as part of a command submission. Optional

`interface_views`: [InterfaceView](#) (repeated)

Interface views specified in the transaction filter. Includes an `InterfaceView` for each interface for which there is a `InterfaceFilter` with

- its party in the `witness_parties` of this event,
- and which is implemented by the template of this event,
- and which has `include_interface_view` set.

Optional

`witness_parties`: [string](#) (repeated)

The parties that are notified of this event. When a `CreatedEvent` is returned as part of a transaction tree, this will include all the parties specified in the `TransactionFilter` that are informees of the event. If served as part of a flat transaction those will be limited to all parties specified in the `TransactionFilter` that are stakeholders of the contract (i.e. either signatories or observers).

In case of v2 API, if the `CreatedEvent` is returned as part of an `AssignedEvent`, `ActiveContract` or `IncompleteUnassigned` (so the event is related to an assignment or unassignment): this will include all parties of the `TransactionFilter` that are stakeholders of the contract.

Required

`signatories`: [string](#) (repeated)

The signatories for this contract as specified by the template. Required

`observers`: [string](#) (repeated)

The observers for this contract as specified explicitly by the template or implicitly as choice controllers. This field never contains parties that are signatories. Required

`agreement_text`: [google.protobuf.StringValue](#)

The agreement text of the contract. We use `StringValue` to properly reflect optionality on the wire for backwards compatibility. This is necessary since the empty string is an acceptable (and in fact the default) agreement text, but also the default string in protobuf. This means a newer client works with an older sandbox seamlessly. Optional

`created_at`: [google.protobuf.Timestamp](#)

Ledger effective time of the transaction that created the contract. Required

Event message, v1

An event in the flat transaction stream can either be the creation or the archiving of a contract.

In the transaction service the events are restricted to the events visible for the parties specified in the transaction filter. Each event message type below contains a `witness_parties` field which indicates the subset of the requested parties that can see the event in question. In the flat transaction stream you'll only receive events that have witnesses.

oneof `event.created`: [CreatedEvent](#)

oneof `event.archived`: [ArchivedEvent](#)

ExercisedEvent message, v1

Records that a choice has been exercised on a target contract.

`event_id`: [string](#)

The ID of this particular event. Must be a valid LedgerString (as described in `value.proto`). Required

`contract_id`: [string](#)

The ID of the target contract. Must be a valid LedgerString (as described in `value.proto`). Required

`template_id`: [Identifier](#)

The template of the target contract. The identifier uses the package-id reference format, with the package id at which the contract was created.

Required

`package_name`: [google.protobuf.StringValue](#)

The package name of the created contract. Optional

`interface_id`: [Identifier](#)

The interface where the choice is defined, if inherited. If defined, the identifier uses the package-id reference format.

Optional

`choice`: [string](#)

The choice that was exercised on the target contract. Must be a valid NameString (as described in `value.proto`). Required

`choice_argument`: [Value](#)

The argument of the exercised choice. Required

`acting_parties`: [string](#) (repeated)

The parties that exercised the choice. Each element must be a valid `PartyIdString` (as described in `value.proto`). Required

consuming: [bool](#)

If true, the target contract may no longer be exercised. Required

witness_parties: [string](#) (repeated)

The parties that are notified of this event. The witnesses of an exercise node will depend on whether the exercise was consuming or not. If consuming, the witnesses are the union of the stakeholders and the actors. If not consuming, the witnesses are the union of the signatories and the actors. Note that the actors might not necessarily be observers and thus signatories. This is the case when the controllers of a choice are specified using `flexible controllers`, using the `choice ... controller` syntax, and said controllers are not explicitly marked as observers. Each element must be a valid `PartyIdString` (as described in `value.proto`). Required

child_event_ids: [string](#) (repeated)

References to further events in the same transaction that appeared as a result of this `ExercisedEvent`. It contains only the immediate children of this event, not all members of the subtree rooted at this node. The order of the children is the same as the event order in the transaction. Each element must be a valid `LedgerString` (as described in `value.proto`). Optional

exercise_result: [Value](#)

The result of exercising the choice. Required

choice_package_id: [google.protobuf.StringValue](#)

The package of the choice that was exercised, which may be different from the package with which the contract was created.

Optional

InterfaceView message, v1

View of a create event matched by an interface filter.

interface_id: [Identifier](#)

The interface implemented by the matched event. The identifier uses the package-id reference format.

Required

view_status: [google.rpc.Status](#)

Whether the view was successfully computed, and if not, the reason for the error. The error is reported using the same rules for error codes and messages as the errors returned for API requests. Required

view_value: [Record](#)

The value of the interface's view method on this event. Set if it was requested in the `InterfaceFilter` and it could be successfully computed. Optional

`com/daml/ledger/api/v1/event_query_service.proto`

12.5.8.13 EventQueryService, v1

Query events by contract id or key.

GetEventsByContractId method, v1

Get the create and the consuming exercise event for the contract with the provided ID. No events will be returned for contracts that have been pruned because they have already been archived before the latest pruning offset.

Request: [GetEventsByContractIdRequest](#)

Response: [GetEventsByContractIdResponse](#)

GetEventsByContractKey method, v1

Get all create and consuming exercise events for the contracts with the provided contract key. Only events for unpruned contracts will be returned. Matching events are delivered in reverse chronological order, i.e., the most recent events are delivered first.

Request: [GetEventsByContractKeyRequest](#)

Response: [GetEventsByContractKeyResponse](#)

GetEventsByContractIdRequest message, v1

`contract_id`: [string](#)

The contract id being queried. Required

`requesting_parties`: [string](#) (repeated)

The parties whose events the client expects to see. The events associated with the contract id will only be returned if the requesting parties includes at least one party that is a stakeholder of the event. For a definition of stakeholders see <https://docs.daml.com/concepts/ledger-model/ledger-privacy.html#contract-observers-and-stakeholders> Required

GetEventsByContractIdResponse message, v1

`create_event`: [CreatedEvent](#)

The create event for the contract with the `contract_id` given in the request provided it exists and has not yet been pruned. Optional

`archive_event`: [ArchivedEvent](#)

The archive event for the contract with the `contract_id` given in the request provided such an archive event exists and it has not yet been pruned. Optional

GetEventsByContractKeyRequest message, v1

contract_key: [Value](#)

The contract key to search for. Required

template_id: [Identifier](#)

The template id associated with the contract key Both package-name and package-id reference formats for the identifier are supported.

Required

requesting_parties: [string](#) (repeated)

The parties whose events the client expects to see. The events associated with the contract key will only be returned if the requesting parties includes at least one party that is a stakeholder of the event. For a definition of stakeholders see <https://docs.daml.com/concepts/ledger-model/ledger-privacy.html#contract-observers-and-stakeholders> To gain visibility of all contract key bindings and to ensure consistent performance use a key maintainer as a requesting party. Required

continuation_token: [string](#)

A continuation_token associated with a previous response. Optional

GetEventsByContractKeyResponse message, v1

create_event: [CreatedEvent](#)

The most recent create event for a contract with the key given in the request, if no continuation_token is provided. If a continuation_token is provided, then this is the most recent create event preceding the create event whose continuation_token was provided. Optional

archive_event: [ArchivedEvent](#)

The archive event for the create event provided the created contract is archived. Optional

continuation_token: [string](#)

If the continuation_token is populated then there may be additional events available. To retrieve these events use the continuation_token in a subsequent request. Optional

com/daml/ledger/api/v1/experimental_features.proto

AcsActiveAtOffsetFeature message, v1

Whether the Ledger API supports requesting ACS at an offset

supported: [bool](#)

CommandDeduplicationFeatures message, v1

Feature descriptors for command deduplication intended to be used for adapting Ledger API tests.

deduplication_period_support: [CommandDeduplicationPeriodSupport](#)

deduplication_type: [CommandDeduplicationType](#)

max_deduplication_duration_enforced: [bool](#)

The ledger will reject any requests which specify a deduplication period which exceeds the specified max deduplication duration. This is also enforced for ledgers that convert deduplication periods specified as offsets to durations.

CommandDeduplicationPeriodSupport message, v1

Feature descriptor specifying how deduplication periods can be specified and how they are handled by the participant node.

offset_support: [CommandDeduplicationPeriodSupport.OffsetSupport](#)

duration_support: [CommandDeduplicationPeriodSupport.DurationSupport](#)

ExperimentalCommandInspectionService message, v1

Whether the Ledger API supports command inspection service

supported: [bool](#)

ExperimentalCommitterEventLog message, v1

How the committer stores events.

event_log_type: [ExperimentalCommitterEventLog.CommitterEventLogType](#)

ExperimentalContractIds message, v1

See [daml-lf/spec/contract-id.rst](#) for more information on contract ID formats.

v1: [ExperimentalContractIds.ContractIdV1Support](#)

ExperimentalExplicitDisclosure message, v1

Enables the use of explicitly disclosed contracts for command submission

supported: [bool](#)

ExperimentalFeatures message, v1

See the feature message definitions for descriptions.

```
self_service_error_codes: ExperimentalSelfServiceErrorCodes
static_time: ExperimentalStaticTime
command_deduplication: CommandDeduplicationFeatures
optional_ledger_id: ExperimentalOptionalLedgerId
contract_ids: ExperimentalContractIds
committer_event_log: ExperimentalCommitterEventLog
explicit_disclosure: ExperimentalExplicitDisclosure
user_and_party_local_metadata_extensions: ExperimentalUserAndPartyLocalMetadataExtensions
acs_active_at_offset: AcsActiveAtOffsetFeature
template_filters: TransactionsWithTemplateFilters
command_inspection_service: ExperimentalCommandInspectionService
pruned_offsets: StreamingPrunedOffsets
```

ExperimentalOptionalLedgerId message, v1

Ledger API does not require ledgerId to be set in the requests.

Message has no fields.

ExperimentalSelfServiceErrorCodes message, v1

GRPC self-service error codes are returned by the Ledger API.

Message has no fields.

ExperimentalStaticTime message, v1

Ledger is in the static time mode and exposes a time service.

```
supported: bool
```

ExperimentalUserAndPartyLocalMetadataExtensions message, v1

Whether the Ledger API supports: - is_deactivated user property, - metadata with annotations and resource version for users and parties, - update calls for users and parties.

supported: *bool*

StreamingPrunedOffsets message, v1

Whether the Ledger API supports streaming pruned offsets in the transaction streams

supported: *bool*

TransactionsWithTemplateFilters message, v1

Whether the Ledger API supports querying for transaction streams using template filters

supported: *bool*

CommandDeduplicationPeriodSupport.DurationSupport enum, v1

How the participant node supports deduplication periods specified as durations.

DURATION_NATIVE_SUPPORT	0	
DURATION_CONVERT_TO_OFFSET	1	

CommandDeduplicationPeriodSupport.OffsetSupport enum, v1

How the participant node supports deduplication periods specified using offsets.

OFFSET_NOT_SUPPORTED	0	
OFFSET_NATIVE_SUPPORT	1	
OFFSET_CONVERT_TO_DURATION	2	

CommandDeduplicationType enum, v1

How the participant node reports duplicate command submissions.

ASYNC_ONLY	0	Duplicate commands are exclusively reported asynchronously via completions.
ASYNC_AND_CONCURRENT_SYNC	1	Commands that are duplicates of concurrently submitted commands are reported synchronously via a gRPC error on the command submission, while all other duplicate commands are reported asynchronously via completions.

ExperimentalCommitterEventLog.CommitterEventLogType enum, v1

CENTRAL-IZED	0	Default. There is a single log.
DIS-TRIBUTED	1	There is more than one event log. Usually, when the committer itself is distributed. Or there are per-participant event logs. It may result in transaction IDs being different for the same transaction across participants, for example.

ExperimentalContractIds.ContractIdV1Support enum, v1

SUFFIXED	0	Contract IDs must be suffixed. Distributed ledger implementations must reject non-suffixed contract IDs.
NON_SUFFIXED	1	Contract IDs do not need to be suffixed. This can be useful for shorter contract IDs in centralized committer implementations. Suffixed contract IDs must also be supported.

`com/daml/ledger/api/v1/ledger_configuration_service.proto`

12.5.8.14 LedgerConfigurationService, v1

LedgerConfigurationService allows clients to subscribe to changes of the ledger configuration. In V2 Ledger API this service is not available anymore.

GetLedgerConfiguration method, v1

Returns the latest configuration as the first response, and publishes configuration updates in the same stream.

Request: [GetLedgerConfigurationRequest](#)

Response: [GetLedgerConfigurationResponse](#)

GetLedgerConfigurationRequest message, v1

`ledger_id`: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

GetLedgerConfigurationResponse message, v1

ledger_configuration: [LedgerConfiguration](#)

The latest ledger configuration.

LedgerConfiguration message, v1

LedgerConfiguration contains parameters of the ledger instance that may be useful to clients.

max_deduplication_duration: [google.protobuf.Duration](#)

If a command submission specifies a deduplication period of length up to `max_deduplication_duration`, the submission SHOULD not be rejected with `FAILED_PRECONDITION` because the deduplication period starts too early. The deduplication period is measured on a local clock of the participant or Daml ledger, and therefore subject to clock skews and clock drifts. Command submissions with longer periods MAY get accepted though.

com/daml/ledger/api/v1/ledger_identity_service.proto

12.5.8.15 LedgerIdentityService, v1

DEPRECATED: This service is now deprecated and ledger identity string is optional for all Ledger API requests.

Allows clients to verify that the server they are communicating with exposes the ledger they wish to operate on. In V2 Ledger API this service is not available anymore.

GetLedgerIdentity method, v1

Clients may call this RPC to return the identifier of the ledger they are connected to.

Request: [GetLedgerIdentityRequest](#)

Response: [GetLedgerIdentityResponse](#)

GetLedgerIdentityRequest message, v1

Message has no fields.

GetLedgerIdentityResponse message, v1

ledger_id: [string](#)

The ID of the ledger exposed by the server. Must be a valid LedgerString (as described in `value.proto`). Optional

com/daml/ledger/api/v1/ledger_offset.proto

LedgerOffset message, v1

Describes a specific point on the ledger.

The Ledger API endpoints that take offsets allow to specify portions of the ledger that are relevant for the client to read.

Offsets returned by the Ledger API can be used as-is (e.g. to keep track of processed transactions and provide a restart point to use in case of need).

The format of absolute offsets is opaque to the client: no client-side transformation of an offset is guaranteed to return a meaningful offset.

The server implementation ensures internally that offsets are lexicographically comparable.

oneof value.absolute: [string](#)

The format of this string is specific to the ledger and opaque to the client.

oneof value.boundary: [LedgerOffset.LedgerBoundary](#)

LedgerOffset.LedgerBoundary enum, v1

LEDGER_BEGIN	0	Refers to the first transaction.
LEDGER_END	1	Refers to the currently last transaction, which is a moving target.

com/daml/ledger/api/v1/package_service.proto

12.5.8.16 PackageService, v1

Allows clients to query the Daml-LF packages that are supported by the server.

ListPackages method, v1

Returns the identifiers of all supported packages.

Request: [ListPackagesRequest](#)

Response: [ListPackagesResponse](#)

GetPackage method, v1

Returns the contents of a single package.

Request: [GetPackageRequest](#)

Response: [GetPackageResponse](#)

GetPackageStatus method, v1

Returns the status of a single package.

Request: [GetPackageStatusRequest](#)

Response: [GetPackageStatusResponse](#)

GetPackageRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

package_id: [string](#)

The ID of the requested package. Must be a valid PackageIdString (as described in `value.proto`). Required

GetPackageResponse message, v1

hash_function: [HashFunction](#)

The hash function we use to calculate the hash. Required

archive_payload: [bytes](#)

Contains a `daml_lf` ArchivePayload. See further details in `daml_lf.proto`. Required

hash: [string](#)

The hash of the archive payload, can also used as a `package_id`. Must be a valid PackageIdString (as described in `value.proto`). Required

GetPackageStatusRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

package_id: [string](#)

The ID of the requested package. Must be a valid PackageIdString (as described in `value.proto`). Required

GetPackageStatusResponse message, v1

package_status: [PackageStatus](#)

The status of the package.

ListPackagesRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

ListPackagesResponse message, v1

package_ids: [string](#) (repeated)

The IDs of all Daml-LF packages supported by the server. Each element must be a valid PackageId-String (as described in `value.proto`). Required

HashFunction enum, v1

SHA256	0	
--------	---	--

PackageStatus enum, v1

UNKNOWN	0	The server is not aware of such a package.
REGISTERED	1	The server is able to execute Daml commands operating on this package.

`com/daml/ledger/api/v1/testing/time_service.proto`

12.5.8.17 TimeService, v1/testing

Optional service, exposed for testing static time scenarios.

GetTime method, v1/testing

Returns a stream of time updates. Always returns at least one response, where the first one is the current time. Subsequent responses are emitted whenever the ledger server's time is updated.

Request: [GetTimeRequest](#)

Response: [GetTimeResponse](#)

SetTime method, v1/testing

Allows clients to change the ledger's clock in an atomic get-and-set operation.

Request: [SetTimeRequest](#)

Response: [.google.protobuf.Empty](#)

GetTimeRequest message, v1/testing

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as describe in `value.proto`). Optional

GetTimeResponse message, v1/testing

current_time: [google.protobuf.Timestamp](#)

The current time according to the ledger server.

SetTimeRequest message, v1/testing

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as describe in `value.proto`). Optional

current_time: [google.protobuf.Timestamp](#)

MUST precisely match the current time as it's known to the ledger server.

new_time: [google.protobuf.Timestamp](#)

The time the client wants to set on the ledger. MUST be a point int time after `current_time`.

`com/daml/ledger/api/v1/trace_context.proto`

TraceContext message, v1

traceparent: [google.protobuf.StringValue](#)

<https://www.w3.org/TR/trace-context/>

tracestate: [google.protobuf.StringValue](#)

com/daml/ledger/api/v1/transaction.proto

Transaction message, v1

Filtered view of an on-ledger transaction's create and archive events.

transaction_id: [string](#)

Assigned by the server. Useful for correlating logs. Must be a valid LedgerString (as described in `value.proto`). Required

command_id: [string](#)

The ID of the command which resulted in this transaction. Missing for everyone except the submitting party. Must be a valid LedgerString (as described in `value.proto`). Optional

workflow_id: [string](#)

The workflow ID used in command submission. Must be a valid LedgerString (as described in `value.proto`). Optional

effective_at: [google.protobuf.Timestamp](#)

Ledger effective time. Must be a valid LedgerString (as described in `value.proto`). Required

events: [Event](#) (repeated)

The collection of events. Only contains `CreatedEvent` or `ArchivedEvent`. Required

offset: [string](#)

The absolute offset. The format of this field is described in `ledger_offset.proto`. Required

trace_context: [TraceContext](#)

Optional; ledger api trace context

The trace context transported in this message corresponds to the trace context supplied by the client application in a HTTP2 header of the original command submission. We typically use a header to transfer this type of information. Here we use message body, because it is used in gRPC streams which do not support per message headers. This field will be populated with the trace context contained in the original submission. If that was not provided, a unique ledger-api-server generated trace context will be used instead.

TransactionTree message, v1

Complete view of an on-ledger transaction.

transaction_id: [string](#)

Assigned by the server. Useful for correlating logs. Must be a valid LedgerString (as described in `value.proto`). Required

command_id: [string](#)

The ID of the command which resulted in this transaction. Missing for everyone except the submitting party. Must be a valid LedgerString (as described in `value.proto`). Optional

workflow_id: [string](#)

The workflow ID used in command submission. Only set if the `workflow_id` for the command was set. Must be a valid LedgerString (as described in `value.proto`). Optional

effective_at: [google.protobuf.Timestamp](#)

Ledger effective time. Required

offset: [string](#)

The absolute offset. The format of this field is described in `ledger_offset.proto`. Required

events_by_id: [TransactionTree.EventsByIdEntry](#) (repeated)

Changes to the ledger that were caused by this transaction. Nodes of the transaction tree. Each key be a valid LedgerString (as describe in `value.proto`). Required

root_event_ids: [string](#) (repeated)

Roots of the transaction tree. Each element must be a valid LedgerString (as describe in `value.proto`). The elements are in the same order as the commands in the corresponding `Commands` object that triggered this transaction. Required

trace_context: [TraceContext](#)

Optional; ledger api trace context

The trace context transported in this message corresponds to the trace context supplied by the client application in a HTTP2 header of the original command submission. We typically use a header to transfer this type of information. Here we use message body, because it is used in gRPC streams which do not support per message headers. This field will be populated with the trace context contained in the original submission. If that was not provided, a unique ledger-api-server generated trace context will be used instead.

TransactionTree.EventsByIdEntry message, v1

key: [string](#)

value: [TreeEvent](#)

TreeEvent message, v1

Each tree event message type below contains a `witness_parties` field which indicates the subset of the requested parties that can see the event in question.

Note that transaction trees might contain events with `_no_` witness parties, which were included simply because they were children of events which have witnesses.

oneof `kind.created`: [CreatedEvent](#)

oneof `kind.exercised`: [ExercisedEvent](#)

`com/daml/ledger/api/v1/transaction_filter.proto`

Filters message, v1

The union of a set of contract filters, or a wildcard.

inclusive: [InclusiveFilters](#)

If set, then contracts matching any of the `InclusiveFilters` match this filter. If not set, or if `InclusiveFilters` has empty `template_ids` and empty `interface_filters`: any contract matches this filter. Optional

InclusiveFilters message, v1

A filter that matches all contracts that are either an instance of one of the `template_ids` or that match one of the `interface_filters`.

`template_ids`: [Identifier](#) (repeated)

A collection of templates for which the data will be included in the `create_arguments` of a matching `CreatedEvent`. SHOULD NOT contain duplicates. All `template_ids` need to be valid: corresponding templates should be defined in one of the available packages at the time of the query. Deprecated in favor of the `template_filters`. If the `template_filters` field is set, the `template_ids` field is ignored. Optional

`interface_filters`: [InterfaceFilter](#) (repeated)

Include an `InterfaceView` for every `InterfaceFilter` matching a contract. The `InterfaceFilter` instances MUST each use a unique `interface_id`. Optional

`template_filters`: [TemplateFilter](#) (repeated)

A collection of templates for which the data will be included in the `create_arguments` of a matching `CreatedEvent`. SHOULD NOT contain duplicate templates. In contrast to the `template_ids` field, one can specify whether the create event payloads should be provided alongside the create arguments. If a contract is simultaneously selected by a template filter and one or more interface filters, the corresponding `include_created_event_blob` are consolidated using an OR operation. Optional

InterfaceFilter message, v1

This filter matches contracts that implement a specific interface.

`interface_id`: [Identifier](#)

The interface that a matching contract must implement. The `interface_id` needs to be valid: corresponding interface should be defined in one of the available packages at the time of the query. Both package-name and package-id reference formats for the identifier are supported.

Required

`include_interface_view`: [bool](#)

Whether to include the interface view on the contract in the returned `CreatedEvent`. Use this to access contract data in a uniform manner in your API client. Optional

`include_created_event_blob`: [bool](#)

Whether to include a `created_event_blob` in the returned `CreatedEvent`. Use this to access the contract create event payload in your API client for submitting it as a disclosed contract with future commands. Optional

TemplateFilter message, v1

This filter matches contracts of a specific template.

`template_id`: [Identifier](#)

A template for which the payload should be included in the response. The `template_id` needs to be valid: corresponding template should be defined in one of the available packages at the time of the query. Both package-name and package-id reference formats for the identifier are supported.

Required

`include_created_event_blob`: [bool](#)

Whether to include a `created_event_blob` in the returned `CreatedEvent`. Use this to access the contract event payload in your API client for submitting it as a disclosed contract with future commands. Optional

TransactionFilter message, v1

A filter both for filtering create and archive events as well as for filtering transaction trees.

`filters_by_party`: [TransactionFilter.FiltersByPartyEntry](#) (repeated)

Each key must be a valid `PartyIdString` (as described in `value.proto`). The interpretation of the filter depends on the stream being filtered:

1. For **transaction tree streams** only party filters with wildcards are allowed, and all subtrees whose root has one of the listed parties as an informee are returned.
2. For **transaction and active-contract-set streams** create and archive events are returned for all contracts whose stakeholders include at least one of the listed parties and match the per-party filter.

Required

TransactionFilter.FiltersByPartyEntry message, v1

key: [string](#)

value: [Filters](#)

com/daml/ledger/api/v1/transaction_service.proto

12.5.8.18 TransactionService, v1

Allows clients to read transactions from the ledger. In V2 Ledger API this service is not available anymore. Use `v2.UpdateService` instead.

GetTransactions method, v1

Read the ledger's filtered transaction stream for a set of parties. Lists only creates and archives, but not other events. Omits all events on transient contracts, i.e., contracts that were both created and archived in the same transaction.

Request: [GetTransactionsRequest](#)

Response: [GetTransactionsResponse](#)

GetTransactionTrees method, v1

Read the ledger's complete transaction tree stream for a set of parties. The stream can be filtered only by parties, but not templates (template filter must be empty).

Request: [GetTransactionsRequest](#)

Response: [GetTransactionTreesResponse](#)

GetTransactionByEventId method, v1

Lookup a transaction tree by the ID of an event that appears within it. For looking up a transaction instead of a transaction tree, please see `GetFlatTransactionByEventId`

Request: [GetTransactionByEventIdRequest](#)

Response: [GetTransactionResponse](#)

GetTransactionById method, v1

Lookup a transaction tree by its ID. For looking up a transaction instead of a transaction tree, please see `GetFlatTransactionById`

Request: [GetTransactionByIdRequest](#)

Response: [GetTransactionResponse](#)

GetFlatTransactionByEventId method, v1

Lookup a transaction by the ID of an event that appears within it.

Request: [GetTransactionByEventIdRequest](#)

Response: [GetFlatTransactionResponse](#)

GetFlatTransactionById method, v1

Lookup a transaction by its ID.

Request: [GetTransactionByIdRequest](#)

Response: [GetFlatTransactionResponse](#)

GetLedgerEnd method, v1

Get the current ledger end. Subscriptions started with the returned offset will serve transactions created after this RPC was called.

Request: [GetLedgerEndRequest](#)

Response: [GetLedgerEndResponse](#)

GetLatestPrunedOffsets method, v1

Get the latest successfully pruned ledger offsets

Request: [GetLatestPrunedOffsetsRequest](#)

Response: [GetLatestPrunedOffsetsResponse](#)

GetFlatTransactionResponse message, v1

transaction: [Transaction](#)

GetLatestPrunedOffsetsRequest message, v1

Empty for now, but may contain fields in the future.

Message has no fields.

GetLatestPrunedOffsetsResponse message, v1

`participant_pruned_up_to_inclusive`: [LedgerOffset](#)

The offset up to which the ledger has been pruned, disregarding the state of all divulged contracts pruning.

`all_divulged_contracts_pruned_up_to_inclusive`: [LedgerOffset](#)

The offset up to which all divulged events have been pruned on the ledger. It can be at or before the `participant_pruned_up_to_inclusive` offset. For more details about all divulged events pruning, see `PruneRequest.prune_all_divulged_contracts` in `participant_pruning_service.proto`.

GetLedgerEndRequest message, v1

`ledger_id`: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as describe in `value.proto`). Optional

GetLedgerEndResponse message, v1

`offset`: [LedgerOffset](#)

The absolute offset of the current ledger end.

GetTransactionByEventIdRequest message, v1

`ledger_id`: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

`event_id`: [string](#)

The ID of a particular event. Must be a valid LedgerString (as described in `value.proto`). Required

`requesting_parties`: [string](#) (repeated)

The parties whose events the client expects to see. Events that are not visible for the parties in this collection will not be present in the response. Each element must be a valid PartyIdString (as described in `value.proto`). Required

GetTransactionByIdRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as describe in `value.proto`). Optional

transaction_id: [string](#)

The ID of a particular transaction. Must be a valid LedgerString (as describe in `value.proto`). Required

requesting_parties: [string](#) (repeated)

The parties whose events the client expects to see. Events that are not visible for the parties in this collection will not be present in the response. Each element be a valid PartyIdString (as describe in `value.proto`). Required

GetTransactionResponse message, v1

transaction: [TransactionTree](#)

GetTransactionTreesResponse message, v1

transactions: [TransactionTree](#) (repeated)

The list of transaction trees that matches the filter in `GetTransactionsRequest` for the `GetTransactionTrees` method.

pruned_offset: [string](#)

Current pruned offset. It is sent when following three conditions are met: - a pruning operation has completed - the transaction stream tails the `LEDGER_END` - the `send_pruned_offsets` field was set on the corresponding request. The conditions for including the `pruned_offset` in messages may change in the future implementations. When `pruned_offset` is set, the message does not contain any transactions in the `transactions` field.

GetTransactionsRequest message, v1

ledger_id: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

begin: [LedgerOffset](#)

Beginning of the requested ledger section. This offset is exclusive: the response will only contain transactions whose offset is strictly greater than this. Required

end: [LedgerOffset](#)

End of the requested ledger section. This offset is inclusive: the response will only contain transactions whose offset is less than or equal to this. Optional, if not set, the stream will not terminate.

filter: [TransactionFilter](#)

Requesting parties with template filters. Template filters must be empty for `GetTransactionTrees` requests. Required

`verbose`: [bool](#)

If enabled, values served over the API will contain more information than strictly necessary to interpret the data. In particular, setting the `verbose` flag to true triggers the ledger to include labels for record fields. Optional

`send_pruned_offsets`: [bool](#)

If set to true, the server will send responses containing pruned offset upon pruning completion. Optional

GetTransactionsResponse message, v1

`transactions`: [Transaction](#) (repeated)

The list of transactions that matches the filter in `GetTransactionsRequest` for the `GetTransactions` method.

`pruned_offset`: [string](#)

Current pruned offset. It is sent when following three conditions are met: - a pruning operation has completed - the transaction stream tails the `LEDGER_END` - the `send_pruned_offsets` field was set on the corresponding request. The conditions for including the `pruned_offset` in messages may change in the future implementations. When `pruned_offset` is set, the message does not contain any transactions in the `transactions` field.

`com/daml/ledger/api/v1/value.proto`

Enum message, v1

A value with finite set of alternative representations.

`enum_id`: [Identifier](#)

Omitted from the transaction stream when verbose streaming is not enabled. Optional when submitting commands.

`constructor`: [string](#)

Determines which of the Variant's alternatives is encoded in this message. Must be a valid `NameString`. Required

GenMap message, v1

entries: [GenMap.Entry](#) (repeated)

GenMap.Entry message, v1

key: [Value](#)

value: [Value](#)

Identifier message, v1

Unique identifier of an entity. Throughout this API, the following terminology is being used:

if a Daml package-id is encoded in the package_id field, it is referred to as using a package-id reference format

if a Daml package-name is encoded in the package_id field, it is referred to as using a package-name reference format

package_id: [string](#)

Generally, the identifier of the Daml package that contains the entity. When encoding a package-id, it must be a valid `PackagedIdString`.

The field is overloaded to also be able to contain the package-name of the Daml package. This is supported if the entity referenced is either an interface or template. When representing the Daml package-name, the encoding is of form `#<package-name>` where `#` (not a valid package-id character) is used as a discriminator for signalling a package-name encoding.

Required

module_name: [string](#)

The dot-separated module name of the identifier. Required

entity_name: [string](#)

The dot-separated name of the entity (e.g. record, template,) within the module. Required

List message, v1

A homogenous collection of values.

elements: [Value](#) (repeated)

The elements must all be of the same concrete value type. Optional

Map message, v1

entries : [Map.Entry](#) (repeated)

Map.Entry message, v1

key : [string](#)

value : [Value](#)

Optional message, v1

Corresponds to Java's Optional type, Scala's Option, and Haskell's Maybe. The reason why we need to wrap this in an additional message is that we need to be able to encode the None case in the Value oneof.

value : [Value](#)

optional

Record message, v1

Contains nested values.

record_id : [Identifier](#)

Omitted from the transaction stream when verbose streaming is not enabled. Optional when submitting commands.

fields : [RecordField](#) (repeated)

The nested values of the record. Required

RecordField message, v1

A named nested value within a record.

label : [string](#)

When reading a transaction stream, it's omitted if verbose streaming is not enabled. When submitting a command, it's optional:

- if all keys within a single record are present, the order in which fields appear does not matter. however, each key must appear exactly once.

- if any of the keys within a single record are omitted, the order of fields MUST match the order of declaration in the Daml template.

Must be a valid NameString

value : [Value](#)

A nested value of a record. Required

Value message, v1

Encodes values that the ledger accepts as command arguments and emits as contract arguments.

The values encoding use different classes of non-empty strings as identifiers. Those classes are defined as follows: - NameStrings are strings with length ≤ 1000 that match the regexp `[A-Za-z_][A-Za-z0-9_]*`. - PackageIdStrings are strings with length ≤ 64 that match the regexp `[A-Za-z0-9_]+`. - PartyIdStrings are strings with length ≤ 255 that match the regexp `[A-Za-z0-9:_]+`. - LedgerStrings are strings with length ≤ 255 that match the regexp `[A-Za-z0-9#:_/_]+`. - ApplicationIdStrings are strings with length ≤ 255 that match the regexp `[A-Za-z0-9#:_/_ @\|]+`.

oneof Sum.record: [Record](#)

oneof Sum.variant: [Variant](#)

oneof Sum.contract_id: [string](#)

Identifier of an on-ledger contract. Commands which reference an unknown or already archived contract ID will fail. Must be a valid LedgerString.

oneof Sum.list: [List](#)

Represents a homogeneous list of values.

oneof Sum.int64: [sint64](#)

oneof Sum.numeric: [string](#)

A Numeric, that is a decimal value with precision 38 (at most 38 significant digits) and a scale between 0 and 37 (significant digits on the right of the decimal point). The field has to match the regex:

```
[+-]?[0-9]{1,38}(\.[0-9]{0,37})?
```

and should be representable by a Numeric without loss of precision.

oneof Sum.text: [string](#)

A string.

oneof Sum.timestamp: [sfixed64](#)

Microseconds since the UNIX epoch. Can go backwards. Fixed since the vast majority of values will be greater than 2^{28} , since currently the number of microseconds since the epoch is greater than that. Range: 0001-01-01T00:00:00Z to 9999-12-31T23:59:59.999999Z, so that we can convert to/from <https://www.ietf.org/rfc/rfc3339.txt>

oneof Sum.party: [string](#)

An agent operating on the ledger. Must be a valid PartyIdString.

oneof Sum.bool: [bool](#)

True or false.

oneof Sum.unit: [google.protobuf.Empty](#)

This value is used for example for choices that don't take any arguments.

oneof Sum.date: [int32](#)

Days since the unix epoch. Can go backwards. Limited from 0001-01-01 to 9999-12-31, also to be compatible with <https://www.ietf.org/rfc/rfc3339.txt>

oneof Sum.optional: [Optional](#)

The Optional type, None or Some

oneof Sum.map: [Map](#)

The Map type

oneof Sum.enum: [Enum](#)

The Enum type

oneof Sum.gen_map: [GenMap](#)

The GenMap type

[Variant message, v1](#)

A value with alternative representations.

variant_id: [Identifier](#)

Omitted from the transaction stream when verbose streaming is not enabled. Optional when submitting commands.

constructor: [string](#)

Determines which of the Variant's alternatives is encoded in this message. Must be a valid NameString. Required

value: [Value](#)

The value encoded within the Variant. Required

com/daml/ledger/api/v1/version_service.proto

[12.5.8.19 VersionService, v1](#)

Allows clients to retrieve information about the ledger API version

[GetLedgerApiVersion method, v1](#)

Read the Ledger API version

Request: [GetLedgerApiVersionRequest](#)

Response: [GetLedgerApiVersionResponse](#)

FeaturesDescriptor message, v1

`user_management`: [UserManagementFeature](#)

If set, then the Ledger API server supports user management. It is recommended that clients query this field to gracefully adjust their behavior for ledgers that do not support user management.

`party_management`: [PartyManagementFeature](#)

If set, then the Ledger API server supports party management configurability. It is recommended that clients query this field to gracefully adjust their behavior to maximum party page size.

`experimental`: [ExperimentalFeatures](#)

Features under development or features that are used for ledger implementation testing purposes only.

Daml applications SHOULD not depend on these in production.

GetLedgerApiVersionRequest message, v1

`ledger_id`: [string](#)

Must correspond to the ledger ID reported by the Ledger Identification Service. Must be a valid Ledger-String (as described in `value.proto`). Optional

GetLedgerApiVersionResponse message, v1

`version`: [string](#)

The version of the ledger API.

`features`: [FeaturesDescriptor](#)

The features supported by this Ledger API endpoint.

Daml applications CAN use the feature descriptor on top of version constraints on the Ledger API version to determine whether a given Ledger API endpoint supports the features required to run the application.

See the feature descriptions themselves for the relation between Ledger API versions and feature presence.

PartyManagementFeature message, v1

`max_parties_page_size`: [int32](#)

The maximum number of parties the server can return in a single response (page).

UserManagementFeature message, v1

supported: [bool](#)

Whether the Ledger API server provides the user management service.

max_rights_per_user: [int32](#)

The maximum number of rights that can be assigned to a single user. Servers MUST support at least 100 rights per user. A value of 0 means that the server enforces no rights per user limit.

max_users_page_size: [int32](#)

The maximum number of users the server can return in a single response (page). Servers MUST support at least a 100 users per page. A value of 0 means that the server enforces no page size limit.

com/daml/ledger/api/v2/command_completion_service.proto

12.5.8.20 CommandCompletionService, v2

Allows clients to observe the status of their submissions. Commands may be submitted via the Command Submission Service. The on-ledger effects of their submissions are disclosed by the Update Service.

Commands may fail in 2 distinct manners:

1. Failure communicated synchronously in the gRPC error of the submission.
2. Failure communicated asynchronously in a Completion, see [completion.proto](#).

Note that not only successfully submitted commands MAY produce a completion event. For example, the participant MAY choose to produce a completion event for a rejection of a duplicate command.

Clients that do not receive a successful completion about their submission MUST NOT assume that it was successful. Clients SHOULD subscribe to the CompletionStream before starting to submit commands to prevent race conditions.

CompletionStream method, v2

Subscribe to command completion events.

Request: [CompletionStreamRequest](#)

Response: [CompletionStreamResponse](#)

CompletionStreamRequest message, v2

application_id: [string](#)

Only completions of commands submitted with the same application_id will be visible in the stream. Must be a valid ApplicationIdString (as described in [value.proto](#)). Required unless authentication is used with a user token or a custom token specifying an application-id. In that case, the token's user-id, respectively application-id, will be used for the request's application_id.

parties: [string](#) (repeated)

Non-empty list of parties whose data should be included. Only completions of commands for which at least one of the `act_as` parties is in the given set of parties will be visible in the stream. Must be a valid `PartyIdString` (as described in `value.proto`). Required

`begin_exclusive`: [ParticipantOffset](#)

This field indicates the minimum offset for completions. This can be used to resume an earlier completion stream. Optional, if not set the ledger uses the current ledger end offset instead.

CompletionStreamResponse message, v2

`checkpoint`: [com.daml.ledger.api.v1.Checkpoint](#)

This checkpoint may be used to restart consumption. The checkpoint belongs to the completion in this response. Required

`completion`: [Completion](#)

Required

`domain_id`: [string](#)

The sequencing domain. In case

- successful/failed transactions: identifies the sequencing domain of the transaction
- for successful/failed unassign commands: identifies the source domain
- for successful/failed assign commands: identifies the target domain

Required

`com/daml/ledger/api/v2/command_service.proto`

12.5.8.21 CommandService, v2

Command Service is able to correlate submitted commands with completion data, identify timeouts, and return contextual information with each tracking result. This supports the implementation of stateless clients.

Note that submitted commands generally produce completion events as well, even in case a command gets rejected. For example, the participant SHOULD produce a completion event for a rejection of a duplicate command.

SubmitAndWait method, v2

Submits a single composite command and waits for its result. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [.google.protobuf.Empty](#)

SubmitAndWaitForUpdateId method, v2

Submits a single composite command, waits for its result, and returns the update id. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [SubmitAndWaitForUpdateIdResponse](#)

SubmitAndWaitForTransaction method, v2

Submits a single composite command, waits for its result, and returns the transaction. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [SubmitAndWaitForTransactionResponse](#)

SubmitAndWaitForTransactionTree method, v2

Submits a single composite command, waits for its result, and returns the transaction tree. Propagates the gRPC error of failed submissions including Daml interpretation errors.

Request: [SubmitAndWaitRequest](#)

Response: [SubmitAndWaitForTransactionTreeResponse](#)

SubmitAndWaitForTransactionResponse message, v2

transaction: [Transaction](#)

The flat transaction that resulted from the submitted command. Required

completion_offset: [string](#)

The format of this field is described in `participant_offset.proto`. Optional

SubmitAndWaitForTransactionTreeResponse message, v2

transaction: [TransactionTree](#)

The transaction tree that resulted from the submitted command. Required

completion_offset: [string](#)

The format of this field is described in `participant_offset.proto`. Optional

SubmitAndWaitForUpdateIdResponse message, v2

update_id: [string](#)

The id of the transaction that resulted from the submitted command. Must be a valid LedgerString (as described in `value.proto`). Required

completion_offset: [string](#)

The format of this field is described in `participant_offset.proto`. Optional

SubmitAndWaitRequest message, v2

These commands are atomic, and will become transactions.

commands: [Commands](#)

The commands to be submitted. Required

`com/daml/ledger/api/v2/command_submission_service.proto`

12.5.8.22 CommandSubmissionService, v2

Allows clients to attempt advancing the ledger's state by submitting commands. The final states of their submissions are disclosed by the Command Completion Service. The on-ledger effects of their submissions are disclosed by the Update Service.

Commands may fail in 2 distinct manners:

1. Failure communicated synchronously in the gRPC error of the submission.
2. Failure communicated asynchronously in a Completion, see `completion.proto`.

Note that not only successfully submitted commands MAY produce a completion event. For example, the participant MAY choose to produce a completion event for a rejection of a duplicate command.

Clients that do not receive a successful completion about their submission MUST NOT assume that it was successful. Clients SHOULD subscribe to the CompletionStream before starting to submit commands to prevent race conditions.

Submit method, v2

Submit a single composite command.

Request: [SubmitRequest](#)

Response: [SubmitResponse](#)

SubmitReassignment method, v2

Submit a single reassignment.

Request: [SubmitReassignmentRequest](#)

Response: [SubmitReassignmentResponse](#)

SubmitReassignmentRequest message, v2

reassignment_command: [ReassignmentCommand](#)

The reassignment command to be submitted. Required

SubmitReassignmentResponse message, v2

Message has no fields.

SubmitRequest message, v2

The submitted commands will be processed atomically in a single transaction. Moreover, each Command in `commands` will be executed in the order specified by the request.

commands: [Commands](#)

The commands to be submitted in a single transaction. Required

SubmitResponse message, v2

Message has no fields.

`com/daml/ledger/api/v2/commands.proto`

Commands message, v2

A composite command that groups multiple commands together.

workflow_id: [string](#)

Identifier of the on-ledger workflow that this command is a part of. Must be a valid LedgerString (as described in `value.proto`). Optional

application_id: [string](#)

Uniquely identifies the application or participant user that issued the command. Must be a valid ApplicationIdString (as described in `value.proto`). Required unless authentication is used with a user token or a custom token specifying an application-id. In that case, the token's user-id, respectively application-id, will be used for the request's application_id.

command_id: [string](#)

Uniquely identifies the command. The triple (`application_id`, `party + act_as`, `command_id`) constitutes the change ID for the intended ledger change, where `party + act_as` is interpreted as a set of party names. The change ID can be used for matching the intended ledger changes with all their completions. Must be a valid `LedgerString` (as described in `value.proto`). Required

`party`: [string](#)

Party on whose behalf the command should be executed. If ledger API authorization is enabled, then the authorization metadata must authorize the sender of the request to act on behalf of the given party. Must be a valid `PartyIdString` (as described in `value.proto`). Deprecated in favor of the `act_as` field. If both are set, then the effective list of parties on whose behalf the command should be executed is the union of all parties listed in `party` and `act_as`. Optional

`commands`: [com.daml.ledger.api.v1.Command](#) (repeated)

Individual elements of this atomic command. Must be non-empty. Required

`oneof deduplication_period.deduplication_duration`: [google.protobuf.Duration](#)

Specifies the length of the deduplication period. It is interpreted relative to the local clock at some point during the submission's processing. Must be non-negative. Must not exceed the maximum deduplication time (see `ledger_configuration_service.proto`).

`oneof deduplication_period.deduplication_offset`: [string](#)

Specifies the start of the deduplication period by a completion stream offset (exclusive). Must be a valid `LedgerString` (as described in `participant_offset.proto`).

`min_ledger_time_abs`: [google.protobuf.Timestamp](#)

Lower bound for the ledger time assigned to the resulting transaction. Note: The ledger time of a transaction is assigned as part of command interpretation. Use this property if you expect that command interpretation will take a considerable amount of time, such that by the time the resulting transaction is sequenced, its assigned ledger time is not valid anymore. Must not be set at the same time as `min_ledger_time_rel`. Optional

`min_ledger_time_rel`: [google.protobuf.Duration](#)

Same as `min_ledger_time_abs`, but specified as a duration, starting from the time the command is received by the server. Must not be set at the same time as `min_ledger_time_abs`. Optional

`act_as`: [string](#) (repeated)

Set of parties on whose behalf the command should be executed. If ledger API authorization is enabled, then the authorization metadata must authorize the sender of the request to act on behalf of each of the given parties. This field supersedes the `party` field. The effective set of parties on whose behalf the command should be executed is the union of all parties listed in `party` and `act_as`, which must be non-empty. Each element must be a valid `PartyIdString` (as described in `value.proto`). Optional

`read_as`: [string](#) (repeated)

Set of parties on whose behalf (in addition to all parties listed in `act_as`) contracts can be retrieved. This affects Daml operations such as `fetch`, `fetchByKey`, `lookupByKey`, `exercise`, and `exerciseByKey`. Note: A participant node of a Daml network can host multiple parties. Each contract present on the participant node is only visible to a subset of these parties. A command can only use contracts that are visible to at least one of the parties in `act_as` or `read_as`. This visibility check is independent from the Daml authorization rules for fetch operations. If ledger API authorization is

enabled, then the authorization metadata must authorize the sender of the request to read contract data on behalf of each of the given parties. Optional

submission_id: *string*

A unique identifier to distinguish completions for different submissions with the same change ID. Typically a random UUID. Applications are expected to use a different UUID for each retry of a submission with the same change ID. Must be a valid LedgerString (as described in `value.proto`).

If omitted, the participant or the committer may set a value of their choice. Optional

disclosed_contracts: *com.daml.ledger.api.v1.DisclosedContract* (repeated)

Additional contracts used to resolve contract & contract key lookups. Optional

domain_id: *string*

Must be a valid domain ID Required

package_id_selection_preference: *string* (repeated)

The package-id selection preference of the client for resolving package names and interface instances in command submission and interpretation

`com/daml/ledger/api/v2/completion.proto`

Completion message, v2

A completion represents the status of a submitted command on the ledger: it can be successful or failed.

command_id: *string*

The ID of the succeeded or failed command. Must be a valid LedgerString (as described in `value.proto`). Required

status: *google.rpc.Status*

Identifies the exact type of the error. It uses the same format of conveying error details as it is used for the RPC responses of the APIs. Optional

update_id: *string*

The update_id of the transaction or reassignment that resulted from the command with command_id. Only set for successfully executed commands. Must be a valid LedgerString (as described in `value.proto`).

application_id: *string*

The application-id or user-id that was used for the submission, as described in `commands.proto`. Must be a valid ApplicationIdString (as described in `value.proto`). Optional for historic completions where this data is not available.

act_as: *string* (repeated)

The set of parties on whose behalf the commands were executed. Contains the union of `party` and `act_as` from `commands.proto`. The order of the parties need not be the same as in the submission. Each element must be a valid PartyIdString (as described in `value.proto`). Optional for historic completions where this data is not available.

`submission_id`: [string](#)

The submission ID this completion refers to, as described in `commands.proto`. Must be a valid `LedgerString` (as described in `value.proto`). Optional

`oneof deduplication_period.deduplication_offset`: [string](#)

Specifies the start of the deduplication period by a completion stream offset (exclusive).

Must be a valid `LedgerString` (as described in `value.proto`).

`oneof deduplication_period.deduplication_duration`: [google.protobuf.Duration](#)

Specifies the length of the deduplication period. It is measured in record time of completions.

Must be non-negative.

`trace_context`: [com.daml.ledger.api.v1.TraceContext](#)

Optional; ledger api trace context

The trace context transported in this message corresponds to the trace context supplied by the client application in a HTTP2 header of the original command submission. We typically use a header to transfer this type of information. Here we use message body, because it is used in gRPC streams which do not support per message headers. This field will be populated with the trace context contained in the original submission. If that was not provided, a unique ledger-api-server generated trace context will be used instead.

`com/daml/ledger/api/v2/event_query_service.proto`

12.5.8.23 EventQueryService, v2

Query events by contract id.

Note that querying by contract key is not (yet) supported, as contract keys are not supported (yet) in multi-domain scenarios.

GetEventsByContractId method, v2

Get the create and the consuming exercise event for the contract with the provided ID. No events will be returned for contracts that have been pruned because they have already been archived before the latest pruning offset.

Request: [com.daml.ledger.api.v1.GetEventsByContractIdRequest](#)

Response: [GetEventsByContractIdResponse](#)

Archived message, v2

archived_event: [com.daml.ledger.api.v1.ArchivedEvent](#)

Required

domain_id: [string](#)

Required The domain which sequenced the archival of the contract

Created message, v2

created_event: [com.daml.ledger.api.v1.CreatedEvent](#)

Required

domain_id: [string](#)

The domain which sequenced the creation of the contract Required

GetEventsByContractIdResponse message, v2

created: [Created](#)

The create event for the contract with the `contract_id` given in the request provided it exists and has not yet been pruned. Optional

archived: [Archived](#)

The archive event for the contract with the `contract_id` given in the request provided such an archive event exists and it has not yet been pruned. Optional

`com/daml/ledger/api/v2/package_service.proto`

12.5.8.24 PackageService, v2

Allows clients to query the Daml-LF packages that are supported by the server.

ListPackages method, v2

Returns the identifiers of all supported packages.

Request: [ListPackagesRequest](#)

Response: [com.daml.ledger.api.v1.ListPackagesResponse](#)

GetPackage method, v2

Returns the contents of a single package.

Request: [GetPackageRequest](#)

Response: [.com.daml.ledger.api.v1.GetPackageResponse](#)

GetPackageStatus method, v2

Returns the status of a single package.

Request: [GetPackageStatusRequest](#)

Response: [.com.daml.ledger.api.v1.GetPackageStatusResponse](#)

GetPackageRequest message, v2

package_id: [string](#)

The ID of the requested package. Must be a valid PackageIdString (as described in `value.proto`).
Required

GetPackageStatusRequest message, v2

package_id: [string](#)

The ID of the requested package. Must be a valid PackageIdString (as described in `value.proto`).
Required

ListPackagesRequest message, v2

Message has no fields.

`com/daml/ledger/api/v2/participant_offset.proto`

ParticipantOffset message, v2

Describes a specific point on the participant. This is a participant local value: a participant offset is meaningful only in the context of its participant. Different participants may associate different offsets to the same change synchronized over a domain, and conversely, the same literal participant offset may refer to different changes on different participants.

This is also a unique index of the changes which happened on the virtual shared ledger. Participant offset define an order, which is the same in which order the updates are visible as subscribing to the `UpdateService`. This ordering is also a fully causal ordering for one specific domain: for two updates synchronized by the same domain, the one with a bigger participant offset happened after than the one with a smaller participant offset. Please note this is not true for updates synchronized by a different domain. Accordingly, the participant offset order may deviate from the order of the changes on the virtual shared ledger.

The Ledger API endpoints that take offsets allow to specify portions of the participant that are relevant for the client to read.

Offsets returned by the Ledger API can be used as-is (e.g. to keep track of processed transactions and provide a restart point to use in case of need).

The format of absolute offsets is opaque to the client: no client-side transformation of an offset is guaranteed to return a meaningful offset.

The server implementation ensures internally that offsets are lexicographically comparable.

oneof value.absolute: [string](#)

The format of this string is specific to the participant and opaque to the client.

oneof value.boundary: [ParticipantOffset.ParticipantBoundary](#)

[ParticipantOffset.ParticipantBoundary enum, v2](#)

PARTICIPANT_BEGIN	0	Refers to the first transaction.
PARTICIPANT_END	1	Refers to the currently last transaction, which is a moving target.

`com/daml/ledger/api/v2/reassignment.proto`

[AssignedEvent message, v2](#)

Records that a contract has been assigned, and it can be used on the target domain.

source: [string](#)

The ID of the source domain. Must be a valid domain ID. Required

target: [string](#)

The ID of the target domain. Must be a valid domain ID. Required

unassign_id: [string](#)

The ID from the unassigned event. For correlation capabilities. For one contract the (unassign_id, source domain) pair is unique. Must be a valid LedgerString (as described in `value.proto`). Required

submitter: [string](#)

Party on whose behalf the assign command was executed. Empty if the assignment happened offline via the repair service. Must be a valid PartyIdString (as described in `value.proto`). Optional

reassignment_counter: [uint64](#)

Each corresponding assigned and unassigned event has the same reassignment_counter. This strictly increases with each unassign command for the same contract. Creation of the contract corresponds to reassignment_counter equals zero. Required

created_event: [com.daml.ledger.api.v1.CreatedEvent](#)

Required

Reassignment message, v2

Complete view of an on-ledger reassignment.

update_id: [string](#)

Assigned by the server. Useful for correlating logs. Must be a valid LedgerString (as described in `value.proto`). Required

command_id: [string](#)

The ID of the command which resulted in this reassignment. Missing for everyone except the submitting party on the submitting participant. Must be a valid LedgerString (as described in `value.proto`). Optional

workflow_id: [string](#)

The workflow ID used in reassignment command submission. Only set if the `workflow_id` for the command was set. Must be a valid LedgerString (as described in `value.proto`). Optional

offset: [string](#)

The absolute offset. The format of this field is described in `participant_offset.proto`. Required

oneof event.unassigned_event: [UnassignedEvent](#)

oneof event.assigned_event: [AssignedEvent](#)

trace_context: [com.daml.ledger.api.v1.TraceContext](#)

Optional; ledger api trace context

The trace context transported in this message corresponds to the trace context supplied by the client application in a HTTP2 header of the original command submission. We typically use a header to transfer this type of information. Here we use message body, because it is used in gRPC streams which do not support per message headers. This field will be populated with the trace context contained in the original submission. If that was not provided, a unique ledger-api-server generated trace context will be used instead.

UnassignedEvent message, v2

Records that a contract has been unassigned, and it becomes unusable on the source domain

unassign_id: [string](#)

The ID of the unassignment. This needs to be used as an input for a assign ReassignmentCommand. For one contract the (unassign_id, source domain) pair is unique. Must be a valid LedgerString (as described in `value.proto`). Required

contract_id: [string](#)

The ID of the reassigned contract. Must be a valid LedgerString (as described in `value.proto`). Required

template_id: [com.daml.ledger.api.v1.Identifier](#)

The template of the reassigned contract. Required

source: [string](#)

The ID of the source domain Must be a valid domain ID Required

target: [string](#)

The ID of the target domain Must be a valid domain ID Required

submitter: [string](#)

Party on whose behalf the unassign command was executed. Empty if the unassignment happened offline via the repair service. Must be a valid PartyIdString (as described in `value.proto`). Optional

reassignment_counter: [uint64](#)

Each corresponding assigned and unassigned event has the same reassignment_counter. This strictly increases with each unassign command for the same contract. Creation of the contract corresponds to reassignment_counter equals zero. Required

assignment_exclusivity: [google.protobuf.Timestamp](#)

Assignment exclusivity Before this time (measured on the target domain), only the submitter of the unassignment can initiate the assignment Defined for reassigning participants. Optional

witness_parties: [string](#) (repeated)

The parties that are notified of this event. Required

`com/daml/ledger/api/v2/reassignment_command.proto`

AssignCommand message, v2

Assign a contract

unassign_id: [string](#)

The ID from the unassigned event to be completed by this assignment. Must be a valid LedgerString (as described in `value.proto`). Required

source: [string](#)

The ID of the source domain Must be a valid domain ID Required

target: [string](#)

The ID of the target domain Must be a valid domain ID Required

ReassignmentCommand message, v2

workflow_id: [string](#)

Identifier of the on-ledger workflow that this command is a part of. Must be a valid LedgerString (as described in `value.proto`). Optional

application_id: [string](#)

Uniquely identifies the application or participant user that issued the command. Must be a valid ApplicationIdString (as described in `value.proto`). Required unless authentication is used with a

user token or a custom token specifying an application-id. In that case, the token's user-id, respectively application-id, will be used for the request's application_id.

command_id: [string](#)

Uniquely identifies the command. The triple (application_id, submitter, command_id) constitutes the change ID for the intended ledger change. The change ID can be used for matching the intended ledger changes with all their completions. Must be a valid LedgerString (as described in `value.proto`). Required

submitter: [string](#)

Party on whose behalf the command should be executed. If ledger API authorization is enabled, then the authorization metadata must authorize the sender of the request to act on behalf of the given party. Must be a valid PartyIdString (as described in `value.proto`). Required

oneof command.unassign_command: [UnassignCommand](#)

oneof command.assign_command: [AssignCommand](#)

submission_id: [string](#)

A unique identifier to distinguish completions for different submissions with the same change ID. Typically a random UUID. Applications are expected to use a different UUID for each retry of a submission with the same change ID. Must be a valid LedgerString (as described in `value.proto`).

If omitted, the participant or the committer may set a value of their choice. Optional

[UnassignCommand message, v2](#)

Unassign a contract

contract_id: [string](#)

The ID of the contract the client wants to unassign. Must be a valid LedgerString (as described in `value.proto`). Required

source: [string](#)

The ID of the source domain Must be a valid domain ID Required

target: [string](#)

The ID of the target domain Must be a valid domain ID Required

com/daml/ledger/api/v2/state_service.proto

[12.5.8.25 StateService, v2](#)

Allows clients to get state from the ledger.

GetActiveContracts method, v2

Returns a stream of the snapshot of the active contracts and incomplete reassignments at a ledger offset. If there are no active contracts, the stream returns a single response message with the offset at which the snapshot has been taken. Clients SHOULD use the offset in the last GetActiveContract-sResponse message to continue streaming transactions with the update service. Clients SHOULD NOT assume that the set of active contracts they receive reflects the state at the ledger end.

Request: [GetActiveContractsRequest](#)

Response: [GetActiveContractsResponse](#)

GetConnectedDomains method, v2

Get the list of connected domains at the time of the query.

Request: [GetConnectedDomainsRequest](#)

Response: [GetConnectedDomainsResponse](#)

GetLedgerEnd method, v2

Get the current ledger end. Subscriptions started with the returned offset will serve events after this RPC was called.

Request: [GetLedgerEndRequest](#)

Response: [GetLedgerEndResponse](#)

GetLatestPrunedOffsets method, v2

Get the latest successfully pruned ledger offsets

Request: [GetLatestPrunedOffsetsRequest](#)

Response: [GetLatestPrunedOffsetsResponse](#)

ActiveContract message, v2

`created_event`: [com.daml.ledger.api.v1.CreatedEvent](#)

Required

`domain_id`: [string](#)

A valid domain ID Required

`reassignment_counter`: [uint64](#)

Each corresponding assigned and unassigned event has the same `reassignment_counter`. This strictly increases with each unassign command for the same contract. Creation of the contract corresponds to `reassignment_counter` equals zero. This field will be the `reassignment_counter` of the latest observable activation event on this domain, which is before the `active_at_offset`. Required

GetActiveContractsRequest message, v2

filter: [TransactionFilter](#)

Templates to include in the served snapshot, per party. Required

verbose: [bool](#)

If enabled, values served over the API will contain more information than strictly necessary to interpret the data. In particular, setting the verbose flag to true triggers the ledger to include labels for record fields. Optional

active_at_offset: [string](#)

The offset at which the snapshot of the active contracts will be computed. Must be no greater than the current ledger end offset. Must be greater than or equal to the last pruning offset. If not set the current ledger end offset will be used. Optional

GetActiveContractsResponse message, v2

offset: [string](#)

Included only in the last message. The client should start consuming the transactions endpoint with this offset. The format of this field is described in `participant_offset.proto`.

workflow_id: [string](#)

The workflow ID used in command submission which corresponds to the `contract_entry`. Only set if the `workflow_id` for the command was set. Must be a valid `LedgerString` (as described in `value.proto`). Optional

oneof `contract_entry.active_contract`: [ActiveContract](#)

The contract is active on the given domain, meaning: there was an activation event on the given domain (created, assigned), which is not followed by a deactivation event (archived, unassigned) on the same domain, until the `active_at_offset`. Since activeness is defined as a per domain concept, it is possible, that a contract is active on one domain, but already archived on another. There will be one such message for each domain the contract is active on.

oneof `contract_entry.incomplete_unassigned`: [IncompleteUnassigned](#)

Included iff the unassigned event was before or at the `active_at_offset`, but there was no corresponding assigned event before or at the `active_at_offset`.

oneof `contract_entry.incomplete_assigned`: [IncompleteAssigned](#)

Important: this message is not indicating that the contract is active on the target domain! Included iff the assigned event was before or at the `active_at_offset`, but there was no corresponding unassigned event before or at the `active_at_offset`.

GetConnectedDomainsRequest message, v2

party: [string](#)

The party of interest Must be a valid PartyIdString (as described in `value.proto`). Required

GetConnectedDomainsResponse message, v2

connected_domains: [GetConnectedDomainsResponse.ConnectedDomain](#) (repeated)

GetConnectedDomainsResponse.ConnectedDomain message, v2

domain_alias: [string](#)

The alias of the domain Required

domain_id: [string](#)

The ID of the domain Required

permission: [ParticipantPermission](#)

The permission on the domain Required

GetLatestPrunedOffsetsRequest message, v2

Empty for now, but may contain fields in the future.

Message has no fields.

GetLatestPrunedOffsetsResponse message, v2

participant_pruned_up_to_inclusive: [ParticipantOffset](#)

The offset up to which the ledger has been pruned, disregarding the state of all divulged contracts pruning.

all_divulged_contracts_pruned_up_to_inclusive: [ParticipantOffset](#)

The offset up to which all divulged events have been pruned on the ledger. It can be at or before the `participant_pruned_up_to_inclusive` offset. For more details about all divulged events pruning, see `PruneRequest.prune_all_divulged_contracts` in `participant_pruning_service.proto`.

GetLedgerEndRequest message, v2

Message has no fields.

GetLedgerEndResponse message, v2

offset: [ParticipantOffset](#)

The absolute offset of the current ledger end.

IncompleteAssigned message, v2

assigned_event: [AssignedEvent](#)

Required

IncompleteUnassigned message, v2

created_event: [com.daml.ledger.api.v1.CreatedEvent](#)

Required

unassigned_event: [UnassignedEvent](#)

Required

ParticipantPermission enum, v2

Enum indicating the permission level that the participant has for the party whose connected domains are being listed.

Submission	0	
Confirmation	1	participant can only confirm transactions
Observation	2	participant can only observe transactions

com/daml/ledger/api/v2/testing/time_service.proto

12.5.8.26 TimeService, v2/testing

Optional service, exposed for testing static time scenarios.

GetTime method, v2/testing

Returns the current time according to the ledger server.

Request: [GetTimeRequest](#)

Response: [GetTimeResponse](#)

SetTime method, v2/testing

Allows clients to change the ledger's clock in an atomic get-and-set operation.

Request: [SetTimeRequest](#)

Response: [.google.protobuf.Empty](#)

GetTimeRequest message, v2/testing

Message has no fields.

GetTimeResponse message, v2/testing

`current_time`: [google.protobuf.Timestamp](#)

The current time according to the ledger server.

SetTimeRequest message, v2/testing

`current_time`: [google.protobuf.Timestamp](#)

MUST precisely match the current time as it's known to the ledger server.

`new_time`: [google.protobuf.Timestamp](#)

The time the client wants to set on the ledger. MUST be a point in time after `current_time`.

`com/daml/ledger/api/v2/transaction.proto`

Transaction message, v2

Filtered view of an on-ledger transaction's create and archive events.

`update_id`: [string](#)

Assigned by the server. Useful for correlating logs. Must be a valid LedgerString (as described in `value.proto`). Required

`command_id`: [string](#)

The ID of the command which resulted in this transaction. Missing for everyone except the submitting party. Must be a valid LedgerString (as described in `value.proto`). Optional

`workflow_id`: [string](#)

The workflow ID used in command submission. Must be a valid LedgerString (as described in `value.proto`). Optional

`effective_at`: [google.protobuf.Timestamp](#)

Ledger effective time. Must be a valid LedgerString (as described in `value.proto`). Required

`events`: [com.daml.ledger.api.v1.Event](#) (repeated)

The collection of events. Only contains `CreatedEvent` or `ArchivedEvent`. Required

`offset`: [string](#)

The absolute offset. The format of this field is described in `participant_offset.proto`. Required

`domain_id`: [string](#)

A valid domain ID. Identifies the domain that synchronized the transaction. Required

`trace_context`: [com.daml.ledger.api.v1.TraceContext](#)

Optional; ledger api trace context

The trace context transported in this message corresponds to the trace context supplied by the client application in a HTTP2 header of the original command submission. We typically use a header to transfer this type of information. Here we use message body, because it is used in gRPC streams which do not support per message headers. This field will be populated with the trace context contained in the original submission. If that was not provided, a unique ledger-api-server generated trace context will be used instead.

TransactionTree message, v2

Complete view of an on-ledger transaction.

`update_id`: [string](#)

Assigned by the server. Useful for correlating logs. Must be a valid LedgerString (as described in `value.proto`). Required

`command_id`: [string](#)

The ID of the command which resulted in this transaction. Missing for everyone except the submitting party. Must be a valid LedgerString (as described in `value.proto`). Optional

`workflow_id`: [string](#)

The workflow ID used in command submission. Only set if the `workflow_id` for the command was set. Must be a valid LedgerString (as described in `value.proto`). Optional

`effective_at`: [google.protobuf.Timestamp](#)

Ledger effective time. Required

`offset`: [string](#)

The absolute offset. The format of this field is described in `participant_offset.proto`. Required

`events_by_id`: [TransactionTree.EventsByIdEntry](#) (repeated)

Changes to the ledger that were caused by this transaction. Nodes of the transaction tree. Each key be a valid LedgerString (as describe in `value.proto`). Required

`root_event_ids`: [string](#) (repeated)

Roots of the transaction tree. Each element must be a valid LedgerString (as describe in `value.proto`). The elements are in the same order as the commands in the corresponding Commands object that triggered this transaction. Required

`domain_id`: [string](#)

A valid domain ID. Identifies the domain that synchronized the transaction. Required

`trace_context`: [com.daml.ledger.api.v1.TraceContext](#)

Optional; ledger api trace context

The trace context transported in this message corresponds to the trace context supplied by the client application in a HTTP2 header of the original command submission. We typically use a header to transfer this type of information. Here we use message body, because it is used in gRPC streams which do not support per message headers. This field will be populated with the trace context contained in the original submission. If that was not provided, a unique ledger-api-server generated trace context will be used instead.

[TransactionTree.EventsByIdEntry message, v2](#)

`key`: [string](#)

`value`: [com.daml.ledger.api.v1.TreeEvent](#)

`com/daml/ledger/api/v2/transaction_filter.proto`

[TransactionFilter message, v2](#)

A filter both for filtering create and archive events as well as for filtering transaction trees.

`filters_by_party`: [TransactionFilter.FiltersByPartyEntry](#) (repeated)

Each key must be a valid PartyIdString (as described in `value.proto`). The interpretation of the filter depends on the stream being filtered:

1. For **transaction tree streams** all party keys used as wildcard filters, and all subtrees whose root has one of the listed parties as an informee are returned. If there are InclusiveFilters, those will

control returned `CreatedEvent` fields were applicable, but not used for template/interface filtering.

2. For **transaction and active-contract-set streams** create and archive events are returned for all contracts whose stakeholders include at least one of the listed parties and match the per-party filter.

Required

TransactionFilter.FiltersByPartyEntry message, v2

key: *string*

value: *com.daml.ledger.api.v1.Filters*

com/daml/ledger/api/v2/update_service.proto

12.5.8.27 UpdateService, v2

Allows clients to read updates (transactions and reassignments) from the ledger.

`GetUpdates` and `GetUpdateTrees` provide a comprehensive stream of updates/changes which happened on the virtual shared ledger. These streams are indexed with ledger offsets, which are strictly increasing. The virtual shared ledger consist of changes happening on multiple domains which are connected to the serving participant. Each update belongs to one domain, this is provided in the result (the `domain_id` field in `Transaction` and `TransactionTree` for transactions, the `source` field in `UnassignedEvent` and the `target` field in `AssignedEvent`). Consumers can rely on strong causal guarantees on the virtual shared ledger for a single domain: updates which have greater offsets are happened after than updates with smaller offsets for the same domain. Across different domains this is not guaranteed.

GetUpdates method, v2

Read the ledger's filtered transaction stream and related reassignments for a set of parties. For transactions it lists only creates and archives, but no other events. Omits all events on transient contracts, i.e., contracts that were both created and archived in the same transaction.

Request: *GetUpdatesRequest*

Response: *GetUpdatesResponse*

GetUpdateTrees method, v2

Read the ledger's complete transaction tree stream and related reassignments for a set of parties. The stream will be filtered only by the parties as wildcard parties. The template/interface filters describe the respective fields in the `CreatedEvent` results.

Request: *GetUpdatesRequest*

Response: *GetUpdateTreesResponse*

GetTransactionTreeByEventId method, v2

Lookup a transaction tree by the ID of an event that appears within it. For looking up a transaction instead of a transaction tree, please see [GetTransactionByEventId](#)

Request: [GetTransactionByEventIdRequest](#)

Response: [GetTransactionTreeResponse](#)

GetTransactionTreeById method, v2

Lookup a transaction tree by its ID. For looking up a transaction instead of a transaction tree, please see [GetTransactionById](#)

Request: [GetTransactionByIdRequest](#)

Response: [GetTransactionTreeResponse](#)

GetTransactionByEventId method, v2

Lookup a transaction by the ID of an event that appears within it.

Request: [GetTransactionByEventIdRequest](#)

Response: [GetTransactionResponse](#)

GetTransactionById method, v2

Lookup a transaction by its ID.

Request: [GetTransactionByIdRequest](#)

Response: [GetTransactionResponse](#)

GetTransactionByEventIdRequest message, v2

`event_id`: [string](#)

The ID of a particular event. Must be a valid `LedgerString` (as described in `value.proto`). Required

`requesting_parties`: [string](#) (repeated)

The parties whose events the client expects to see. Events that are not visible for the parties in this collection will not be present in the response. Each element must be a valid `PartyIdString` (as described in `value.proto`). Required

GetTransactionByIdRequest message, v2

update_id: [string](#)

The ID of a particular transaction. Must be a valid LedgerString (as describe in `value.proto`). Required

requesting_parties: [string](#) (repeated)

The parties whose events the client expects to see. Events that are not visible for the parties in this collection will not be present in the response. Each element be a valid PartyIdString (as describe in `value.proto`). Required

GetTransactionResponse message, v2

transaction: [Transaction](#)

Required

GetTransactionTreeResponse message, v2

transaction: [TransactionTree](#)

Required

GetUpdateTreesResponse message, v2

oneof update.transaction_tree: [TransactionTree](#)

oneof update.reassignment: [Reassignment](#)

pruned_offset: [string](#)

Current pruned offset. It is sent when following three conditions are met: - a pruning operation has completed - the transaction stream tails the LEDGER_END - the `send_pruned_offsets` field was set on the corresponding request. The conditions for including the `pruned_offset` in messages may change in the future implementations. When `pruned_offset` is set, the message does not contain any transactions in the `transactions` field.

GetUpdatesRequest message, v2

begin_exclusive: [ParticipantOffset](#)

Beginning of the requested ledger section. The response will only contain transactions whose offset is strictly greater than this. Required

end_inclusive: [ParticipantOffset](#)

End of the requested ledger section. The response will only contain transactions whose offset is less than or equal to this. Optional, if not set, the stream will not terminate.

filter: [TransactionFilter](#)

Requesting parties with template filters. Template filters must be empty for GetUpdateTrees requests. Required

verbose: [bool](#)

If enabled, values served over the API will contain more information than strictly necessary to interpret the data. In particular, setting the verbose flag to true triggers the ledger to include labels, record and variant type ids for record fields. Optional

send_pruned_offsets: [bool](#)

If set to true, the server will send responses containing pruned offset upon pruning completion. Optional

GetUpdatesResponse message, v2

oneof update.transaction: [Transaction](#)

oneof update.reassignment: [Reassignment](#)

pruned_offset: [string](#)

Current pruned offset. It is sent when following three conditions are met: - a pruning operation has completed - the transaction stream tails the LEDGER_END - the *send_pruned_offsets* field was set on the corresponding request. The conditions for including the *pruned_offset* in messages may change in the future implementations. When *pruned_offset* is set, the message does not contain any transactions in the transactions field.

com/daml/ledger/api/v2/version_service.proto

12.5.8.28 VersionService, v2

Allows clients to retrieve information about the ledger API version

GetLedgerApiVersion method, v2

Read the Ledger API version

Request: [GetLedgerApiVersionRequest](#)

Response: [.com.daml.ledger.api.v1.GetLedgerApiVersionResponse](#)

GetLedgerApiVersionRequest message, v2

Message has no fields.

12.5.9 How Daml Types are Translated to Protobuf

This page gives an overview and reference on how Daml types and contracts are represented by the Ledger API as protobuf messages, most notably:

in the stream of transactions from the [TransactionService, v1](#) as payload for [CreateCommand message, v1](#) and [ExerciseCommand message, v1](#) sent to [CommandSubmissionService, v1](#) and [CommandService, v1](#).

The Daml code in the examples below is written in Daml 1.1.

12.5.9.1 Notation

The notation used on this page for the protobuf messages is the same as you get if you invoke `protoc --decode=Foo < some_payload.bin`. To illustrate the notation, here is a simple definition of the messages `Foo` and `Bar`:

```
message Foo {
  string field_with_primitive_type = 1;
  Bar field_with_message_type = 2;
}

message Bar {
  repeated int64 repeated_field_inside_bar = 1;
}
```

A particular value of `Foo` is then represented by the Ledger API in this way:

```
{ // Foo
  field_with_primitive_type: "some string"
  field_with_message_type { // Bar
    repeated_field_inside_bar: 17
    repeated_field_inside_bar: 42
    repeated_field_inside_bar: 3
  }
}
```

The name of messages is added as a comment after the opening curly brace.

12.5.9.2 Records and Primitive Types

Records or product types are translated to [Record message, v1](#). Here's an example Daml record type that contains a field for each primitive type:

```
data MyProductType = MyProductType with
  intField : Int
  textField : Text
  decimalField : Decimal
```

(continues on next page)

(continued from previous page)

```
boolField : Bool
partyField : Party
timeField : Time
listField : [Int]
contractIdField : ContractId SomeTemplate
```

And here's an example of creating a value of type `MyProductType`:

```
alice <- allocateParty "Alice"
bob <- allocateParty "Bob"
someCid <- submit alice do createCmd SomeTemplate with owner=alice

let myProduct = MyProductType with
    intField = 17
    textField = "some text"
    decimalField = 17.42
    boolField = False
    partyField = bob
    timeField = datetime 2018 May 16 0 0 0
    listField = [1,2,3]
    contractIdField = someCid
```

For this data, the respective data on the Ledger API is shown below. Note that this value would be enclosed by a particular contract containing a field of type `MyProductType`. See [Contract templates](#) for the translation of Daml contracts to the representation by the Ledger API.

```
{ // Record
  record_id { // Identifier
    package_id: "some-hash"
    name: "Types.MyProductType"
  }
  fields { // RecordField
    label: "intField"
    value { // Value
      int64: 17
    }
  }
  fields { // RecordField
    label: "textField"
    value { // Value
      text: "some text"
    }
  }
  fields { // RecordField
    label: "decimalField"
    value { // Value
      decimal: "17.42"
    }
  }
  fields { // RecordField
    label: "boolField"
    value { // Value
      bool: false
    }
  }
}
```

(continues on next page)

(continued from previous page)

```

fields { // RecordField
  label: "partyField"
  value { // Value
    party: "Bob"
  }
}
fields { // RecordField
  label: "timeField"
  value { // Value
    timestamp: 1526428800000000
  }
}
fields { // RecordField
  label: "listField"
  value { // Value
    list { // List
      elements { // Value
        int64: 1
      }
      elements { // Value
        int64: 2
      }
      elements { // Value
        int64: 3
      }
    }
  }
}
fields { // RecordField
  label: "contractIdField"
  value { // Value
    contract_id: "some-contract-id"
  }
}
}

```

12.5.9.3 Variants

Variants or sum types are types with multiple constructors. This example defines a simple variant type with two constructors:

```

data MySumType = MySumConstructor1 Int
                | MySumConstructor2 (Text, Bool)

```

The constructor `MyConstructor1` takes a single parameter of type `Integer`, whereas the constructor `MyConstructor2` takes a tuple with two fields as parameter. The snippet below shows how you can create values with either of the constructors.

```

let mySum1 = MySumConstructor1 17
let mySum2 = MySumConstructor2 ("it's a sum", True)

```

Similar to records, variants are also enclosed by a contract, a record, or another variant.

The snippets below shows the value of `mySum1` and `mySum2` respectively as they would be transmit-

ted on the Ledger API within a contract.

Listing 23: mySum1

```
{ // Value
  variant { // Variant
    variant_id { // Identifier
      package_id: "some-hash"
      name: "Types.MySumType"
    }
    constructor: "MyConstructor1"
    value { // Value
      int64: 17
    }
  }
}
```

Listing 24: mySum2

```
{ // Value
  variant { // Variant
    variant_id { // Identifier
      package_id: "some-hash"
      name: "Types.MySumType"
    }
    constructor: "MyConstructor2"
    value { // Value
      record { // Record
        fields { // RecordField
          label: "sumTextField"
          value { // Value
            text: "it's a sum"
          }
        }
        fields { // RecordField
          label: "sumBoolField"
          value { // Value
            bool: true
          }
        }
      }
    }
  }
}
```

12.5.9.4 Contract Templates

Contract templates are represented as records with the same identifier as the template.

This first example template below contains only the signatory party and a simple choice to exercise:

```
data MySimpleTemplateKey =
  MySimpleTemplateKey
  with
    party: Party
```

(continues on next page)

(continued from previous page)

```

template MySimpleTemplate
  with
    owner: Party
  where
    signatory owner

    key MySimpleTemplateKey owner: MySimpleTemplateKey
    maintainer key.party

```

Create a Contract

Creating contracts is done by sending a [CreateCommand message, v1](#) to the [CommandSubmissionService, v1](#) or the [CommandService, v1](#). The message to create a `MySimpleTemplate` contract with Alice being the owner is shown below:

```

{ // CreateCommand
  template_id { // Identifier
    package_id: "some-hash"
    name: "Templates.MySimpleTemplate"
  }
  create_arguments { // Record
    fields { // RecordField
      label: "owner"
      value { // Value
        party: "Alice"
      }
    }
  }
}

```

Receive a Contract

Contracts are received from the [TransactionService, v1](#) in the form of a [CreatedEvent message, v1](#). The data contained in the event corresponds to the data that was used to create the contract.

```

{ // CreatedEvent
  event_id: "some-event-id"
  contract_id: "some-contract-id"
  template_id { // Identifier
    package_id: "some-hash"
    name: "Templates.MySimpleTemplate"
  }
  create_arguments { // Record
    fields { // RecordField
      label: "owner"
      value { // Value
        party: "Alice"
      }
    }
  }
}

```

(continues on next page)

(continued from previous page)

```
witness_parties: "Alice"
}
```

Exercise a Choice

A choice is exercised by sending an [ExerciseCommand message, v1](#). Taking the same contract template again, exercising the choice `MyChoice` would result in a command similar to the following:

```
{ // ExerciseCommand
  template_id { // Identifier
    package_id: "some-hash"
    name: "Templates.MySimpleTemplate"
  }
  contract_id: "some-contract-id"
  choice: "MyChoice"
  choice_argument { // Value
    record { // Record
      fields { // RecordField
        label: "parameter"
        value { // Value
          int64: 42
        }
      }
    }
  }
}
```

If the template specifies a key, the [ExerciseByKeyCommand message, v1](#) can be used. It works in a similar way as [ExerciseCommand message, v1](#), but instead of specifying the contract identifier you have to provide its key. The example above could be rewritten as follows:

```
{ // ExerciseByKeyCommand
  template_id { // Identifier
    package_id: "some-hash"
    name: "Templates.MySimpleTemplate"
  }
  contract_key { // Value
    record { // Record
      fields { // RecordField
        label: "party"
        value { // Value
          party: "Alice"
        }
      }
    }
  }
}
choice: "MyChoice"
choice_argument { // Value
  record { // Record
    fields { // RecordField
      label: "parameter"
      value { // Value
```

(continues on next page)

(continued from previous page)

```

    int64: 42
  }
}
}
}
}

```

12.5.10 How Daml Types are Translated to Daml-LF

This page shows how types in Daml are translated into Daml-LF. It should help you understand and predict the generated client interfaces, which is useful when you're building a Daml-based application that uses the Ledger API or client bindings in other languages.

For an introduction to Daml-LF, see [Daml-LF](#).

12.5.10.1 Primitive Types

[Built-in data types](#) in Daml have straightforward mappings to Daml-LF.

This section only covers the serializable types, as these are what client applications can interact with via the generated Daml-LF. (Serializable types are ones whose values can exist on the ledger. Function types, `Update` and `Scenario` types and any types built up from these are excluded, and there are several other restrictions.)

Most built-in types have the same name in Daml-LF as in Daml. These are the exact mappings:

Daml primitive type	Daml-LF primitive type
<code>Int</code>	<code>Int64</code>
<code>Time</code>	<code>Timestamp</code>
<code>()</code>	<code>Unit</code>
<code>[]</code>	<code>List</code>
<code>Decimal</code>	<code>Decimal</code>
<code>Text</code>	<code>Text</code>
<code>Date</code>	<code>Date</code>
<code>Party</code>	<code>Party</code>
<code>Optional</code>	<code>Optional</code>
<code>ContractId</code>	<code>ContractId</code>

Be aware that only the Daml primitive types exported by the [Prelude](#) module map to the Daml-LF primitive types above. That means that, if you define your own type named `Party`, it will not translate to the Daml-LF primitive `Party`.

12.5.10.2 Tuple Types

Daml tuple type constructors take types `T1`, `T2`, ..., `TN` to the type `(T1, T2, ..., TN)`. These are exposed in the Daml surface language through the [Prelude](#) module.

The equivalent Daml-LF type constructors are `daml-prim:DA.Types:TupleN`, for each particular `N` (where $2 \leq N \leq 20$). This qualified name refers to the package name (`ghc-prim`) and the module name (`GHC.Tuple`).

For example: the Daml pair type `(Int, Text)` is translated to `daml-prim:DA.Types:Tuple2 Int64 Text`.

12.5.10.3 Data Types

Daml-LF has three kinds of data declarations:

- Record** types, which define a collection of data
- Variant** or **sum** types, which define a number of alternatives
- Enum**, which defines simplified **sum** types without type parameters nor argument.

[Data type declarations in Daml](#) (starting with the `data` keyword) are translated to record, variant or enum types. It's sometimes not obvious what they will be translated to, so this section lists many examples of data types in Daml and their translations in Daml-LF.

Record Declarations

This section uses the syntax for Daml [records](#) with curly braces.

Daml declaration	Daml-LF translation
<code>data Foo = Foo { foo1: Int; foo2: Text }</code>	<code>record Foo □ { foo1: Int64; foo2: Text }</code>
<code>data Foo = Bar { bar1: Int; bar2: Text }</code>	<code>record Foo □ { bar1: Int64; bar2: Text }</code>
<code>data Foo = Foo { foo: Int }</code>	<code>record Foo □ { foo: Int64 }</code>
<code>data Foo = Bar { foo: Int }</code>	<code>record Foo □ { foo: Int64 }</code>
<code>data Foo = Foo {}</code>	<code>record Foo □ {}</code>
<code>data Foo = Bar {}</code>	<code>record Foo □ {}</code>

Variant Declarations

Daml declaration	Daml-LF translation
<code>data Foo = Bar Int Baz Text</code>	<code>variant Foo □ Bar Int64 Baz Text</code>
<code>data Foo a = Bar a Baz Text</code>	<code>variant Foo a □ Bar a Baz Text</code>
<code>data Foo = Bar Unit Baz Text</code>	<code>variant Foo □ Bar Unit Baz Text</code>
<code>data Foo = Bar Unit Baz</code>	<code>variant Foo □ Bar Unit Baz Unit</code>
<code>data Foo a = Bar Baz</code>	<code>variant Foo a □ Bar Unit Baz Unit</code>
<code>data Foo = Foo Int</code>	<code>variant Foo □ Foo Int64</code>
<code>data Foo = Bar Int</code>	<code>variant Foo □ Bar Int64</code>
<code>data Foo = Foo ()</code>	<code>variant Foo □ Foo Unit</code>
<code>data Foo = Bar ()</code>	<code>variant Foo □ Bar Unit</code>
<code>data Foo = Bar { bar: Int } Baz Text</code>	<code>variant Foo □ Bar Foo.Bar Baz Text, record Foo.Bar □ { bar: Int64 }</code>
<code>data Foo = Foo { foo: Int } Baz Text</code>	<code>variant Foo □ Foo Foo.Foo Baz Text, record Foo.Foo □ { foo: Int64 }</code>
<code>data Foo = Bar { bar1: Int; bar2: Decimal } Baz Text</code>	<code>variant Foo □ Bar Foo.Bar Baz Text, record Foo.Bar □ { bar1: Int64; bar2: Decimal }</code>
<code>data Foo = Bar { bar1: Int; bar2: Decimal } Baz { baz1: Text; baz2: Date }</code>	<code>data Foo □ Bar Foo.Bar Baz Foo.Baz, record Foo.Bar □ { bar1: Int64; bar2: Decimal }, record Foo.Baz □ { baz1: Text; baz2: Date }</code>

Enum Declarations

Daml declaration	Daml-LF declaration
<code>data Foo = Bar Baz</code>	<code>enum Foo □ Bar Baz</code>
<code>data Color = Red Green Blue</code>	<code>enum Color □ Red Green Blue</code>

Banned Declarations

There are two gotchas to be aware of: things you might expect to be able to do in Daml that you can't because of Daml-LF.

The first: a single constructor data type must be made unambiguous as to whether it is a record or a variant type. Concretely, the data type declaration `data Foo = Foo` causes a compile-time error, because it is unclear whether it is declaring a record or a variant type.

To fix this, you must make the distinction explicitly. Write `data Foo = Foo {}` to declare a record type with no fields, or `data Foo = Foo ()` for a variant with a single constructor taking unit argument.

The second gotcha is that a constructor in a data type declaration can have at most one unlabelled argument type. This restriction is so that we can provide a straight-forward encoding of Daml-LF

types in a variety of client languages.

Banned declaration	Workaround
<code>data Foo = Foo</code>	<code>data Foo = Foo {}</code> to produce record <code>Foo □ {}</code> OR <code>data Foo = Foo ()</code> to produce variant <code>Foo □ Foo Unit</code>
<code>data Foo = Bar</code>	<code>data Foo = Bar {}</code> to produce record <code>Foo □ {}</code> OR <code>data Foo = Bar ()</code> to produce variant <code>Foo □ Bar Unit</code>
<code>data Foo = Foo Int Text</code>	Name constructor arguments using a record declaration, for example <code>data Foo = Foo { x: Int; y: Text }</code>
<code>data Foo = Bar Int Text</code>	Name constructor arguments using a record declaration, for example <code>data Foo = Bar { x: Int; y: Text }</code>
<code>data Foo = Bar Baz Int Text</code>	Name arguments to the Baz constructor, for example <code>data Foo = Bar Baz { x: Int; y: Text }</code>

12.5.10.4 Type Synonyms

[Type synonyms](#) (starting with the `type` keyword) are eliminated during conversion to Daml-LF. The body of the type synonym is inlined for all occurrences of the type synonym name.

For example, consider the following Daml type declarations.

```
type Username = Text
data User = User { name: Username }
```

The `Username` type is eliminated in the Daml-LF translation, as follows:

```
record User □ { name: Text }
```

12.5.10.5 Template Types

A [template declaration](#) in Daml results in one or more data type declarations behind the scenes. These data types, detailed in this section, are not written explicitly in the Daml program but are created by the compiler.

They are translated to Daml-LF using the same rules as for record declarations above.

These declarations are all at the top level of the module in which the template is defined.

Template Data Types

Every contract template defines a record type for the parameters of the contract. For example, the template declaration:

```
template Iou
  with
    issuer: Party
    owner: Party
    currency: Text
    amount: Decimal
  where
```

results in this record declaration:

```
data Iou = Iou { issuer: Party; owner: Party; currency: Text; amount: Decimal }
```

This translates to the Daml-LF record declaration:

```
record Iou □ { issuer: Party; owner: Party; currency: Text; amount: Decimal }
```

Choice Data Types

Every choice within a contract template results in a record type for the parameters of that choice. For example, let's suppose the earlier `Iou` template has the following choices:

```
nonconsuming choice DoNothing: ()
  controller owner
  do
    return ()

choice Transfer: ContractId Iou
  with newOwner: Party
  controller owner
  do
    updateOwner newOwner
```

This results in these two record types:

```
data DoNothing = DoNothing {}
data Transfer = Transfer { newOwner: Party }
```

Whether the choice is consuming or nonconsuming is irrelevant to the data type declaration. The data type is a record even if there are no fields.

These translate to the Daml-LF record declarations:

```
record DoNothing □ {}
record Transfer □ { newOwner: Party }
```

12.5.10.6 Names with Special Characters

All names in Daml—of types, templates, choices, fields, and variant data constructors—are translated to the more restrictive rules of Daml-LF. ASCII letters, digits, and `_` underscore are unchanged in Daml-LF; all other characters must be mangled in some way, as follows:

`$` changes to `$$`,

Unicode codepoints less than 65536 translate to `$uABCD`, where `ABCD` are exactly four (zero-padded) hexadecimal digits of the codepoint in question, using only lowercase `a–f`, and Unicode codepoints greater translate to `$UABCD1234`, where `ABCD1234` are exactly eight (zero-padded) hexadecimal digits of the codepoint in question, with the same `a–f` rule.

Daml name	Daml-LF identifier
<code>Foo_bar</code>	<code>Foo_bar</code>
<code>baz'</code>	<code>baz\$u0027</code>
<code>:+:</code>	<code>\$u003a\$u002b\$u003a</code>
<code>naïveté</code>	<code>na\$u00efvet\$u00e9</code>
<code>:☐:</code>	<code>\$u003a\$U0001f642\$u003a</code>

12.5.11 Create Your Own Bindings

This page gets you started with creating custom bindings for a Daml Ledger.

Bindings for a language consist of two main components:

Ledger API Client stubs for the programming language, – the remote API that allows sending ledger commands and receiving ledger transactions. You have to generate **Ledger API** from [the gRPC protobuf definitions in the daml repository on GitHub](#). **Ledger API** is documented on this page: [Use the Ledger API With gRPC](#). The [gRPC](#) tutorial explains how to generate client stubs .

Codegen A code generator is a program that generates classes representing Daml contract templates in the language. These classes incorporate all boilerplate code for constructing: [CreateCommand message, v1](#) and [ExerciseCommand message, v1](#) corresponding for each Daml contract template.

Technically codegen is optional. You can construct the commands manually from the auto-generated **Ledger API** classes. However, it is very tedious and error-prone. If you are creating *ad hoc* bindings for a project with a few contract templates, writing a proper codegen may be overkill. On the other hand, if you have hundreds of contract templates in your project or are planning to build language bindings that you will share across multiple projects, we recommend including a codegen in your bindings. It will save you and your users time in the long run.

Note that for different reasons we chose codegen, but that is not the only option. There is really a broad category of metaprogramming features that can solve this problem just as well or even better than codegen; they are language-specific, but often much easier to maintain (i.e. no need to add a build step). Some examples are:

[F# Type Providers](#)
[Template Haskell](#)

12.5.11.1 Build Ledger Commands

No matter what approach you take, either manually building commands or writing a codegen to do this, you need to understand how ledger commands are structured. This section demonstrates how to build create and exercise commands manually and how it can be done using contract classes.

Create Command

Let's recall an **IOU** example from the [Quickstart guide](#), where *iou* template is defined like this:

```
template Iou
  with
    issuer : Party
    owner  : Party
    currency : Text
    amount : Decimal
    observers : [Party]
```

If you do not specify any of the above fields or type their names or values incorrectly, or do not order them exactly as they are in the Daml template, the above code will compile but fail at run-time because you did not structure your create command correctly.

Exercise Command

To build *ExerciseCommand message, v1* for *iou_Transfer*:

```
choice Iou_Transfer : ContractId IouTransfer
  with
    newOwner : Party
  controller owner
  do create IouTransfer with iou = this; newOwner
```

12.5.11.2 Summary

When creating custom bindings for Daml Ledgers, you will need to:

- generate **Ledger API** from the gRPC definitions
- decide whether to write a codegen to generate ledger commands or manually build them for all contracts defined in your Daml model.

The above examples should help you get started. If you are creating custom binding or have any questions, see the [Get Help](#) page for how to get in touch with us.

12.6 Write Off-Ledger Automation Using Daml

12.6.1 Overview

The Daml smart contract language is mostly meant to provide a way to define on-ledger logic, i.e. code that defines how a transaction happens on ledger. Daml is not meant to be used as a general purpose language that can interact with your file system or network; instead, the templates and choices defined with Daml are available to be used by off-ledger logic that interacts with the ledger API. Usually this off-ledger logic is written in a general-purpose language like Java or JavaScript and the codegen allows to interact with models defined in Daml without boilerplate.

However, there are times when it would be nice to write your off-ledger logic in Daml. For relatively simple automations that don't require full access to your system's capabilities, using Daml means that you don't have to map from your on-ledger Daml types and their representation on a separate off-ledger general purpose language (either through the codegen or by manipulating the Protobuf representation of Daml types directly).

There are two tools that allow you to use Daml as an off-ledger language:

Daml Script allows you to write automations that can be triggered by any off-ledger condition, such as the availability of a file in a folder, a message coming from a broker or a user interacting with the system directly.

Ledger Client allows a ledger client to be developed in [Java using ledger bindings](#) and [code generation](#). The client is triggered by on-ledger events, such as the creation of a contract.

Daml Triggers ([deprecated](#)) allow a similar approach but triggered by on-ledger events, such as the creation of a contract.

In their interactions with a traditional database system, Daml Scripts are analogous to SQL scripts. Daml Triggers or ledger clients are analogous to SQL triggers.

12.6.2 React to Off-Ledger Events: Daml Script

Daml Script provides a simple way of testing Daml models and getting quick feedback in Daml studio. In addition to running it in a virtual ledger in [Daml Studio](#), you can also point it against an actual ledger. This means that you can use it for application scripting, to test automation logic and also for [ledger initialization](#).

You can also use Daml Script interactively using [Experiment: Daml REPL \(Deprecated\)](#).

Hint: Remember that you can access all the example code by running `daml new script-example --template script-example`

12.6.2.1 Usage

Our example for this tutorial consists of 2 templates.

First, we have a template called `Coin`:

```
template Coin
  with
    issuer : Party
    owner  : Party
  where
    signatory issuer, owner
```

This template represents a coin issued to `owner` by `issuer`. `Coin` has both the `owner` and the `issuer` as signatories.

Second, we have a template called `CoinProposal`:

```
template CoinProposal
  with
    coin : Coin
  where
    signatory coin.issuer
    observer  coin.owner

    choice Accept : ContractId Coin
      controller coin.owner
      do create coin
```

`CoinProposal` is only signed by the `issuer` and it provides a single `Accept` choice which, when exercised by the controller will create the corresponding `Coin`.

Having defined the templates, we can now move on to write Daml scripts that operate on these templates. To get access to the API used to implement Daml scripts, you need to add the `daml-script` library to the `dependencies` field in `daml.yaml`.

```
dependencies:
  - daml-prim
  - daml-stdlib
  - daml-script
```

We also enable the `ApplicativeDo` extension. We will see below why this is useful.

```
{-# LANGUAGE ApplicativeDo #-}

module ScriptExample where

import DA.Time
import Daml.Script
```

Since on an actual ledger parties cannot be arbitrary strings, we define a record containing all the parties that we will use in our script so that we can easily swap them out.

```
data LedgerParties = LedgerParties with
  bank  : Party
  alice : Party
  bob   : Party
```

Let us now write a function to initialize the ledger with 3 `CoinProposal` contracts and accept 2 of them. This function takes the `LedgerParties` as an argument and returns a value of type `Script ()` which is Daml script's equivalent of `Scenario ()`.

```
initialize : LedgerParties -> Script ()
initialize parties = do
```

First we create the proposals. To do so, we use the `submit` function to submit a transaction. The first argument is the party submitting the transaction. In our case, we want all proposals to be created by the bank so we use `parties.bank`. The second argument must be of type `Commands` so in our case `Commands (ContractId CoinProposal, ContractId CoinProposal, ContractId CoinProposal)` corresponding to the 3 proposals that we create. However, `Commands` requires that the individual commands do not depend on each other. This matches the restriction on the Ledger API where a transaction consists of a list of commands. Using `ApplicativeDo` we can still use `do`-notation as long as we respect this and the last statement in the `do`-block is of the form `return expr` or `pure expr`. In `Commands` we use `createCmd` instead of `create` and `exerciseCmd` instead of `exercise`.

```
(coinProposalAlice, coinProposalBob, coinProposalBank) <- submit parties.bank $
do
  coinProposalAlice <- createCmd (CoinProposal (Coin parties.bank parties.
    alice))
  coinProposalBob <- createCmd (CoinProposal (Coin parties.bank parties.bob))
  coinProposalBank <- createCmd (CoinProposal (Coin parties.bank parties.bank))
  pure (coinProposalAlice, coinProposalBob, coinProposalBank)
```

Now that we have created the `CoinProposals`, we want Alice and Bob to accept the proposal while the Bank will ignore the proposal that it has created for itself. To do so we use separate `submit` statements for Alice and Bob and call `exerciseCmd`.

```
coinAlice <- submit parties.alice $ exerciseCmd coinProposalAlice Accept
coinBob <- submit parties.bob $ exerciseCmd coinProposalBob Accept
```

Finally, we call `pure ()` on the last line of our script to match the type `Script ()`.

```
pure ()
```

Party Management

We have now defined a way to initialize the ledger so we can write a test that checks that the contracts that we expect exist afterwards.

First, we define the signature of our test. We will create the parties used here in the test, so it does not take any arguments.

```
test : Script ()
test = do
```

Now, we create the parties using the `allocateParty` function. This uses the party management service to create new parties with the given display name. Note that the display name does not identify a party uniquely. If you call `allocateParty` twice with the same display name, it will create 2 different parties. This is very convenient for testing since a new party cannot see any old contracts on the ledger so using new parties for each test removes the need to reset the ledger. We factor out party allocation into a function so we can reuse it in later sections.

```
allocateParties : Script LedgerParties
allocateParties = do
  alice <- allocateParty "alice"
  bob <- allocateParty "bob"
  bank <- allocateParty "Bank"
  pure (LedgerParties bank alice bob)
```

We now call the `initialize` function that we defined before on the parties that we have just allocated.

```
initialize parties
```

Queries

To verify the contracts on the ledger, we use the `query` function. We pass it the type of the template and a party. It will then give us all active contracts of the given type visible to the party. In our example, we expect to see one active `CoinProposal` for bank and one `Coin` contract for each of Alice and Bob. We get back list of `(ContractId t, t)` pairs from `query`. In our tests, we do not need the contract ids, so we throw them away using `map snd`.

```
proposals <- query @CoinProposal bank
assertEq [CoinProposal (Coin bank bank)] (map snd proposals)

aliceCoins <- query @Coin alice
assertEq [Coin bank alice] (map snd aliceCoins)

bobCoins <- query @Coin bob
assertEq [Coin bank bob] (map snd bobCoins)
```

Interfaces

To use interfaces within Daml code, the target language version must be at least 1.15.

```
build-options:
  - --target=1.15
```

Now we can define an `Asset` interface which can be implemented by the `Coin` template. We also define `AssetInfo` for use as the viewtype.

```
data AssetInfo = AssetInfo { info : Text } deriving (Eq, Show)

interface Asset where
  viewtype AssetInfo

interface instance Asset for Coin where
  view = AssetInfo { info = "A Coin" }
```

Now we use the `queryInterface` function. We pass it the type of the interface and a party. It will return a list of active contract views for the given interface type. As before we throw away the contract ids using `map snd`.

```
aliceAssets <- queryInterface @Asset alice
assertEq [Some $ AssetInfo "A Coin"] (map snd aliceAssets)
```

Run a Script

To run our script, we first build it with `daml build` and then run it by pointing to the DAR, the name of our script, and the host and port our ledger is running on.

```
daml script --dar .daml/dist/script-example-0.0.1.dar --script-name ScriptExample:test --ledger-host localhost --ledger-port 6865
```

Up to now, we have worked with a script (`test`) that is entirely self-contained. This is fine for running unit-test type script in the IDE, but for more complex use-cases you may want to vary the inputs of a script and inspect its outputs, ideally without having to recompile it. To that end, the `daml script` command supports the flags `--input-file` and `--output-file`. Both flags take a filename, and said file will be read/written as JSON, following the [Daml-LF JSON Encoding](#).

The `--output-file` option instructs `daml script` to write the result of the given `--script-name` to the given filename (creating the file if it does not exist; overwriting it otherwise). This is most useful if the given program has a type `Script b`, where `b` is a meaningful value. In our example, we can use this to write out the party ids that have been allocated by `allocateParties`:

```
daml script --dar .daml/dist/script-example-0.0.1.dar --script-name
ScriptExample:allocateParties --ledger-host localhost --ledger-port 6865
--output-file ledger-parties.json
```

The resulting file will look similar to the following but the actual party IDs will be different each time you run it:

```
{
  "bank": "party-93affbfe-8717-4996-990c-
  ↪9f4c5a889663::12201d00faa0968d7ab81e63ad6ad4ee0d31b08a3581b1d8596e68a1356f27519ccb
  ↪",
  (continues on next page)
```

(continued from previous page)

```

"alice": "party-99595f45-75e3-4373-997c-
↳fbdf899439f7::12201d00faa0968d7ab81e63ad6ad4ee0d31b08a3581b1d8596e68a1356f27519ccb
↳",
"bob": "party-6e38e1ed-c070-4ded-ba20-
↳073e0dbdb13c::12201d00faa0968d7ab81e63ad6ad4ee0d31b08a3581b1d8596e68a1356f27519ccb
↳"
}

```

Next, we want to call the `initialize` function with those parties using the `--input-file` flag. If the `--input-file` flag is specified, the `--script-name` flag must point to a function of one argument returning a `Script`, and the function will be called with the result of parsing the input file as its argument. For example, we can initialize our ledger using the `initialize` function defined above.

Using the previously created `-ledger-parties.json` file, we can initialize our ledger as follows:

```

daml script --dar .daml/dist/script-example-0.0.1.dar --script-name ScriptExample:initialize --ledger-host localhost --ledger-port 6865 --input-file ledger-parties.json

```

12.6.2.2 Use Daml Script for Ledger Initialization

You can use Daml script to initialize a ledger on startup. To do so, specify an `init-script: ScriptExample:initializeUser` field in your `daml.yaml`. This will automatically be picked up by `daml start` and used to initialize sandbox. During development not being able to control party ids can often be inconvenient. Here, we rely on `users` which do put us in control of their id. User ids can be used in Navigator, triggers & other tools instead of party ids.

```

initializeUser : Script ()
initializeUser = do
  parties <- allocateParties
  bank <- validateUserId "bank"
  alice <- validateUserId "alice"
  bob <- validateUserId "bob"
  _ <- createUser (User bank (Some parties.bank)) [CanActAs parties.bank]
  _ <- createUser (User alice (Some parties.alice)) [CanActAs parties.alice]
  _ <- createUser (User bob (Some parties.bob)) [CanActAs parties.bob]
  initialize parties

```

Migrate From Scenarios

Existing scenarios that you used for ledger initialization can be translated to Daml script but there are a few things to keep in mind:

1. You need to add `daml-script` to the list of dependencies in your `daml.yaml`.
2. You need to import the `Daml.Script` module.
3. Calls to `create`, `exercise`, `exerciseByKey` and `createAndExercise` need to be suffixed with `Cmd`, e.g., `createCmd`.
4. Instead of specifying a `scenario` field in your `daml.yaml`, you need to specify an `init-script` field. The initialization script is specified via `Module:identifier` for both fields.

5. In Daml script, `submit` and `submitMustFail` are limited to the functionality provided by the ledger API: A list of independent commands consisting of `createCmd`, `exerciseCmd`, `createAndExerciseCmd` and `exerciseByKeyCmd`. There are two issues you might run into when migrating an existing scenario:
 1. Your commands depend on each other, e.g., you use the result of a `create` within a following command in the same `submit`. In this case, you have two options: If it is not important that they are part of a single transaction, split them into multiple calls to `submit`. If you do need them to be within the same transaction, you can move the logic to a choice and call that using `createAndExerciseCmd`.
 2. You use something that is not part of the 4 ledger API command types, e.g., `fetch`. For `fetch` and `fetchByKey`, you can instead use `queryContractId` and `queryContractKey` with the caveat that they do not run within the same transaction. Other types of `Update` statements can be moved to a choice that you call via `createAndExerciseCmd`.
6. Instead of Scenario's `getParty`, Daml Script provides you with `allocateParty` and `allocatePartyWithHint`. There are a few important differences:
 1. Allocating a party always gives you back a new party (or fails). If you have multiple calls to `getParty` with the same string and expect to get back the same party, you should instead allocate the party once at the beginning and pass it along to the rest of the code.
 2. If you want to allocate a party with a specific party id, you can use `allocatePartyWithHint x (PartyIdHint x)` as a replacement for `getParty x`. Note that while this is supported in Daml Studio, some ledgers can behave differently and ignore the party id hint or interpret it another way. Try to not rely on any specific party id.
7. Instead of `pass` and `passToDate`, Daml Script provides `passTime` and `setTime`.

12.6.2.3 Use Daml Script with the IDE Ledger

Similarly to running `daml test` or when running a script in VSCode itself via the provided buttons, you can use `daml script` to run the scripts in a given DAR file within the IDE Ledger. This is a fully in-memory child process of `daml script`, allowing you to quickly invoke a script without having to spin up a ledger in the background.

To run `daml script` in this mode, you should provide the `--ide-ledger` flag. This flag is not compatible with `--ledger-host`, `--ledger-port`, `--participant-config` (described more in the next section), and `--json-api`. Note that since this uses an in-memory ledger, no state will be preserved once the script finishes. You will only receive a success flag and, optionally, the script result if you use `--output-file`.

12.6.2.4 Use Daml Script in Canton

So far, we have run Daml script against a single participant node. It is also possible to run it in a setting where different parties are hosted on different participant nodes. To do so, pass the `--participant-config participant-config.json` file to `daml script` instead of `--ledger-host` and `ledger-port`. You can generate this file by calling `utils.generate_daml_script_participants_conf(defaultParticipant = Some(one))` in the canton console or in [the bootstrap scripts](#).

The generated file will look similar to the one shown below:

```
{
  "default_participant": {"host": "localhost", "port": 6866},
  "participants": {
```

(continues on next page)

(continued from previous page)

```

    "one": {"host": "localhost", "port": 6866},
    "two": {"host": "localhost", "port": 6865}
  },
  "party_participants": {"alice": "one", "bob": "two"}
}

```

This will define a participant called `one`, declare `one` as the default participant and it defines that the party `alice` is hosted on participant `one`. Whenever you submit something as party, we will use the participant for that party or if none is specified `default_participant`.

If you use `utils.generate_daml_script_participants_conf()` without a default participant, the `default_participant` won't be defined and therefore using a party with an unspecified participant is an error.

`allocateParty` will also use the `default_participant`. If you want to allocate a party on a specific participant, you can use `allocatePartyOn` which accepts the participant name as an extra argument.

Hints for synchronizing contracts on multiple-participant Canton

When you create a contract on `participant1` and try to use it on `participant2`, you can run into synchronization issues where `participant2` doesn't see the contract yet. One option to workaround [this limitation](#) is to poll until the contract is visible. In the example below, the bank and `alice` parties are allocated on two different participants and to avoid synchronization issues, we wait until the contract is visible on `alice` participant.

```

tries : Int
tries = 60

waitForCid : (Template t, HasAgreement t) => Int -> Party -> ContractId t ->
  ↳Script ()
waitForCid tries p cid
  | tries <= 0 = abort $ "Cid " <> show cid <> " did not appear"
  | otherwise = do
    r <- queryContractId p cid
    case r of
      None -> do
        sleep delay
        waitForCid (tries - 1) p cid
      Some _ -> pure ()
    where delay = seconds 1

testWithSync: LedgerParties -> Script ()
testWithSync parties = do
  coinProposalAlice <- submit parties.bank $ createCmd (CoinProposal (Coin
  ↳parties.bank parties.alice))
  waitForCid tries parties.alice coinProposalAlice
  coinAlice <- submit parties.alice $ exerciseCmd coinProposalAlice Accept
  pure ()

```

12.6.2.5 Run Daml Script Against Ledgers with Authorization

To run Daml Script against a ledger that verifies authorization, you need to specify an access token. There are two ways of doing that:

1. Specify a single access token via `--access-token-file path/to/jwt`. This token will then be used for all requests so it must provide claims for all parties that you use in your script.
2. If you need multiple tokens, e.g., because you only have single-party tokens you can define the `access_token` field in the participant config specified via `--participant-config`. Note that you can specify the same participant twice if you want different auth tokens. The file should be of the format

```
{
  "default_participant": {"host": "localhost", "port": 6866, "access_token":
  ↪ "default_jwt", "application_id": "myapp"},
  "participants": {
    "one": {"host": "localhost", "port": 6866, "access_token": "jwt_for_alice
  ↪", "application_id": "myapp"},
    "two": {"host": "localhost", "port": 6865, "access_token": "jwt_for_bob",
  ↪ "application_id": "myapp"}
  },
  "party_participants": {"alice": "one", "bob": "two"}
}
```

If you specify both `--access-token-file` and `--participant-config`, the participant config takes precedence and the token from the file will be used for any participant that does not have a token specified in the config.

12.6.2.6 Run Daml Script Against the HTTP JSON API

In some cases, you only have access to the [HTTP JSON API](#) but not to the gRPC of a ledger, e.g., on [Daml Hub](#). For this use case, Daml script can be run against the JSON API. Note that if you do have access to the gRPC Ledger API, running Daml script against the JSON API does not have any advantages.

To run Daml script against the JSON API you have to pass the `--json-api` parameter to `daml script`. There are a few differences and limitations compared to running Daml Script against the gRPC Ledger API:

1. When running against the JSON API, the `--host` argument has to contain an `http://` or `https://` prefix, e.g., `daml script --host http://localhost --port 7575 --json-api`.
2. The JSON API only supports single-command submissions. This means that within a single call to `submit` you can only execute one ledger API command, e.g., one `createCmd` or one `exerciseCmd`.
3. The JSON API requires authorization tokens even when it is run against a ledger that doesn't verify authorization. The section on [authorization](#) describes how to specify the tokens.
4. The parties used for command submissions and queries must match the parties specified in the token exactly. For command submissions that means `actAs` and `readAs` must match exactly what you specified whereas for queries the union of `actAs` and `readAs` must match the parties specified in the query.
5. If you use multiple parties within your Daml Script, you need to specify one token per party or every submission and query must specify all parties of the multi-party token.
6. `getTime` will always return the Unix epoch in static time mode since the time service is not exposed via the JSON API.

7. `setTime` is not supported and will throw a runtime error.

12.6.3 React to On-Ledger Events: Daml Triggers (Deprecated)

Note: Daml Triggers are deprecated and are not supported in the next major release of Daml Enterprise. So, it is recommended that new applications do not implement Daml Triggers.

In addition to the actual Daml logic which is uploaded to the Ledger and the UI, Daml applications often need to automate certain interactions with the ledger. This is commonly done in the form of a ledger client that listens to the transaction stream of the ledger and when certain conditions are met, e.g., when a template of a given type has been created, the client sends commands to the ledger to create a template of another type.

It is possible to write these clients in a language of your choice, such as JavaScript, using the HTTP JSON API. However, that introduces an additional layer of friction: you now need to translate between the template and choice types in Daml and a representation of those Daml types in the language you are using for your client. Daml triggers address this problem by allowing you to write certain kinds of automation directly in Daml, reusing all the Daml types and logic that you have already defined. Note that, while the logic for Daml triggers is written in Daml, they act like any other ledger client: they are executed separately from the ledger, they do not need to be uploaded to the ledger and they do not allow you to do anything that any other ledger client could not do.

If you don't want to follow along, but still want to get the final code for this section to play with, you can get it by running:

```
daml new --template=gsg-trigger gsg-trigger
```

12.6.3.1 How To Think About Triggers

It is tempting to think of Daml Triggers as snippets of code that `react to ledger events`. However, this is not the best way to think about them; while it will work in some cases, in many corner cases that line of thought will lead to subtle errors.

Instead, you should think of, and write, your triggers from the perspective of `correcting the current ACS` to match some predefined expectations. Trigger rules should be a combination of checking those expectations on the current ACS and applying corrective actions to bring back the ACS in line with its expected state.

The `trigger` part is best thought of as an optimization: rather than check the ACS constantly, we only apply our rules when something happens that we believe may lead to the state of the ledger diverging from our expectations.

12.6.3.2 Sample Trigger

Our example for this tutorial builds upon the Getting Started Guide, specifically picking up right after the [Your First Feature](#) section.

We assume that our requirements are to build a chatbot that responds to every message with:

Please, tell me more about that.

That should fool anyone and pass the Turing test, easily.

As explained above, while the layman description may be “responds to every message”, our technical description is better phrased as “ensure that, at all times, the last message we can see has been sent by us; if that is not the case, the corrective action is to send a response to the last message we can see”.

12.6.3.3 Daml Trigger Basics

A Daml trigger is a regular Daml project that you can build using `daml build`. To get access to the API used to build a trigger, you need to add the `daml-trigger` library to the `dependencies` field in `daml.yaml`:

```
dependencies:
- daml-prim
- daml-stdlib
- daml-script
- daml-trigger
```

Note: In the specific case of the Getting Started Guide, this is already included as part of the `create-daml-app` template.

In addition to that you also need to import the `Daml.Trigger` module in your own code.

Daml triggers automatically track the active contract set (ACS), i.e., the set of contracts that have been created and have not been archived, and the commands in flight for you. In addition to that, they allow you to have user-defined state that is updated based on new transactions and command completions. For our chatbot trigger, the ACS is sufficient, so we will simply use `()` as the type of the user defined state.

To create a trigger you need to define a value of type `Trigger s` where `s` is the type of your user-defined state:

```
data Trigger s = Trigger
  { initialize : TriggerInitializeA s
  , updateState : Message -> TriggerUpdateA s ()
  , rule : Party -> TriggerA s ()
  , registeredTemplates : RegisteredTemplates
  , heartbeat : Optional RelTime
  }
```

To clarify, this is the definition in the `Daml.Trigger` library, reproduced here for illustration purposes. This is not something you need to add to your own code.

The `initialize` function is called on startup and allows you to initialize your user-defined state based on querying the active contract set.

The `updateState` function is called on new transactions and command completions and can be used to update your user-defined state based on the ACS and the transaction or completion. Since our Daml trigger does not have any interesting user-defined state, we will not go into details here.

The `rule` function is the core of a Daml trigger. It defines which commands need to be sent to the ledger based on the party the trigger is executed at, the current state of the ACS, and the user defined state. The type `TriggerA` allows you to emit commands that are then sent to the ledger, query the ACS with `query`, update the user-defined state, as well as retrieve the commands in flight with `getCommandsInFlight`. Like `Scenario` or `Update`, you can use `do` notation and `getTime` with `TriggerA`.

We can specify the templates and interfaces that our trigger will operate on. In our case, we will simply specify `AllInDar` which means that the trigger will receive events for all template and interface types defined in the DAR.

It is also possible to specify an explicit list of templates and interfaces. For example, to only receive events for the `Message` template, one would write:

```
...
registeredTemplates = RegisteredTemplates [registeredTemplate @Message],
...
```

This is mainly useful for performance reasons if your DAR contains many templates and interfaces that are not relevant for your trigger. Note that providing an explicit list of templates and interfaces also filters the result of querying the ACS using the Trigger API: contracts of the excluded templates and interfaces cannot be queried.

Note: In these examples we used templates. Note that interfaces can be passed as well wherever a template is passed, using the same `RegisteredTemplates` type. You are free to pass multiple templates and interfaces and possibly mix the two freely in a single request.

Finally, you can specify an optional heartbeat interval at which the trigger will be sent a `MHeartbeat` message. This is useful if you want to ensure that the trigger is executed at a certain rate to issue timed commands. We will not be using heartbeats in this example.

12.6.3.4 Run a No-Op Trigger

To implement a no-op trigger, one could write the following in a separate `daml/ChatBot.daml` file:

```
module NoOp where

import qualified Daml.Trigger as T

noOp : T.Trigger ()
noOp = T.Trigger with
  initialize = pure ()
  updateState = \_ -> pure ()
  rule = \_ -> do
    debug "triggered"
    pure ()
  registeredTemplates = T.AllInDar
  heartbeat = None
```

In the context of the Getting Started app, if you write the above file, then run `daml start` and `npm start` as usual, and then set up the trigger with:

```
daml trigger --dar .daml/dist/gsg-trigger-0.1.0.dar \  
  --trigger-name NoOp:noOp \  
  --ledger-host localhost \  
  --ledger-port 6865 \  
  --ledger-user "bob"
```

and then play with the app as `alice` and `bob` just like you did for [Your First Feature](#), you should see the trigger command printing a line for each interaction, containing the message triggered as well as other debug information.

12.6.3.5 Diversion: Updating Message

Before we can make our Trigger more useful, we need to think a bit more about what it is supposed to do. For example, we don't want to respond to `bob`'s own messages. We also do not want to send messages when we have not received any.

In order to start with something reasonably simple, we're going to set the rule as

if the last message we can see was not sent by bob, then we'll send "Please, tell me more about that." to whoever sent the last message we can see.

This raises the question of how we can determine which message is the last one, given the current structure of a message. In order to solve that, we need to add a `Time` field to `Message`, which can be done by editing the `Message` template in `daml/User.daml` to look like:

```
template Message with  
  sender: Party  
  receiver: Party  
  content: Text  
  receivedAt: Time  
where  
  signatory sender, receiver
```

This should result in Daml Studio reporting an error in the `SendMessage` choice, as it now needs to set the `receivedAt` field. Here is the updated code for `SendMessage`:

```
-- New definition for SendMessage  
nonconsuming choice SendMessage: ContractId Message with  
  sender: Party  
  content: Text  
  controller sender  
do  
  assertMsg "Designated user must follow you back to send a message" (elem  
← sender following)  
  now <- getTime  
  create Message with sender, receiver = username, content, receivedAt = now
```

The `getTime` action ([doc](#)) returns the time at which the command was received by the sandbox. In more sensitive applications, this may not be sufficiently reliable, as transactions may be processed in parallel (so `receivedAt` timestamp order may not match actual transaction order), and in distributed cases dishonest participants may fudge this value. It's good enough for this example, though.

Now that we have a field to sort on, and thus a way to identify the *latest* message, we can turn our attention back to our trigger code.

12.6.3.6 AutoReply

Open up the trigger code again (`daml/ChatBot.daml`), and change it to:

```
module ChatBot where

import qualified Daml.Trigger as T
import qualified User
import qualified DA.List.Total as List
import DA.Action (when)
import DA.Optional (whenSome)

autoReply : T.Trigger ()
autoReply = T.Trigger
  { initialize = pure ()
  , updateState = \_ -> pure ()
  , rule = \p -> do
      message_contracts <- T.query @User.Message
      let messages = map snd message_contracts
      debug $ "Messages so far: " <> show (length messages)
      let lastMessage = List.maximumOn (.receivedAt) messages
      debug $ "Last message: " <> show lastMessage
      whenSome lastMessage $ \m ->
        when (m.receiver == p) $ do
          users <- T.query @User.User
          debug users
          let isSender = (\user -> user.username == m.sender)
          let replyTo = List.head $ filter (\(_, user) -> isSender user) users
          whenSome replyTo $ \(sender, _) ->
            T.dedupExercise sender (User.SendMessage p "Please, tell me more
↳about that.")
  , registeredTemplates = T.AllInDar
  , heartbeat = None
  }
```

Refresh `daml start` by pressing `r` (followed by Enter on Windows) in its terminal, then start the trigger with:

```
daml trigger --dar .daml/dist/gsg-trigger-0.1.0.dar \
  --trigger-name ChatBot:autoReply \
  --ledger-host localhost \
  --ledger-port 6865 \
  --ledger-user "bob"
```

Play a bit with `alice` and `bob` in your browser, to get a feel for how the trigger works. Watch both the messages in-browser and the debug statements printed by the trigger runner.

Let's walk through the `rule` code line-by-line:

We use the `query` function to get all of the `Message` templates visible to the current party (`p`; in our case this will be `bob`). Per the [documentation](#), this returns a list of tuples (contract id, payload), which we store as `message_contracts`.

We then `map` the `snd` function on the result to get only the payloads, i.e. the actual data of the messages we can see.

We print, as a debug message, the number of messages we can see.

On the next line, get the message with the highest `receivedAt` field (`maximumOn`).

We then print another debug message, this time printing the message our code has identified as the last message visible to the current party. If you run this, you'll see that `lastMessage` is actually a `Optional Message`. This is because the `maximumOn` function will return the element from a list for which the given functions produces the highest value if the list has at least one element, but it needs to still do something sensible if the list is empty; in this case, it would return `None`.

When `lastMessage` is `Some m` (`whenSome`), we execute the given function. Otherwise, `lastMessage` is `None` and we implicitly do nothing.

Next, we need to check whether the message has been sent to or by the party running the trigger (with the current Daml model, it has to be one or the other, as messages are only visible to the sender and receiver). `when` the expression `m.receiver == p` is `True`, our expectations of the ledger state are wrong and we need to correct it. Otherwise, the state matches our rule and we don't need to do anything.

At this point we know the state is `wrong`, per our expectations, and start engaging in correcting actions. For this trigger, this means sending a message to the sender of the last message. In order to do that, we need to find the `User` contract for the sender. We start by getting the list of all `User` contracts we know about, which will be all users who follow the party running the trigger (and that party's own `User` contract). As for `Message` contracts earlier, the result of `query @User` is going to be a list of tuples with (contract id, payload). The big difference is that this time we actually want to keep the contract ids, as that is what we'll use to send a message back.

We print the list of users we just fetched, as a debug message.

We create a function `isSender` to identify the user we are looking for.

We get the user contract by applying our `isSender` function as a `filter` on the list of users, and then taking the `head` of that list, i.e. its first element.

Just like `maximumOn`, `head` will return an `Optional a`, so the next step is to check whether we have actually found the relevant `User` contract. In most cases we should find it, but remember that users can send us a message if we follow *them*, whereas we can only answer if *they* follow *us*.

If we did find some `User` contract to reply to, we extract the corresponding contract id (first element of the tuple, `sender`) and discard the payload (second element, `_`), and we `exercise` the `SendMessage` choice, passing in the current party `p` as the sender. See below for additional information on what that `dedup` in the name of the command means.

12.6.3.7 Command Deduplication

Daml Triggers react to many things, and it's usually important to make sure that the same command is not sent multiple times.

For example, in our `autoReply` chatbot above, the rule will be triggered not only when we receive a message, but also when we send one, as well as when we follow a user or get followed by a user, and when we stop following a user or a user stops following us.

It's easy to imagine a sequence of events that would make a naive trigger implementation send too many messages. For example:

`alice` sends "hi", so the trigger runs and sends an `exercise` command.

`_Before_` the `exercise` command is fully processed, `carol` follows `bob`, which triggers the rule again. The state of all the `Message` contracts `bob` can see has not changed, so the rule might send the response to `alice` again.

We obviously don't want that to happen, as it would likely prevent us from passing that Turing test we were after.

Triggers offer a few features to help users manage that. Possibly the simplest one is the `dedup*` family of ledger operations. When using those, the trigger runner will keep track of the commands currently sent and prevent sending the exact same command again. In the above example, the trigger would see that, when `carol` follows `bob` and the rule runs `dedupExercise`, there is already an `Exercise` command in flight with the exact same value, in this case same message, same sender and same receiver.

Note that, if instead the in-between event is `alice` following `carol`, this simple deduplication mechanism might not work as expected: because the `User` contract ID for `alice` would have changed, the new command is not the same as the in-flight one and thus a second `SendMessage` exercise would be sent to the ledger.

Similarly, if `alice` sends a second message quickly after the first one, this deduplication would prevent it, because the `response` does not have any reference to which message it's responding to. This may or may not be what we want.

If this simple deduplication is not suited to your use-case, you have two other tools at your disposal. The first one is the second argument to the `emitCommands` action ([doc](#)), which is a list of contract IDs. These IDs will be filtered out of any ACS query made by this trigger until the commands submitted as part of the same `emitCommands` call have completed. If your trigger is based on seeing certain contracts, this can be a simple, effective way to prevent triggering it multiple times.

The last tool you have at your disposal is the `getCommandsInflight` action ([doc](#)), which returns all of the commands this instance of the trigger runner has sent and that have not yet been resolved (i.e. either committed or failed). You can then build your own logic based on this list, the ACS, and possibly your own trigger state.

Finally, do keep in mind that all of these mechanisms rely on internal state from the trigger runner, which keeps track of which commands it has sent and for which it's not seen a completion. They will all fail to deduplicate if that internal state is lost, e.g. if the trigger runner is shut down and a new one is started. As such, these deduplication mechanisms should be seen as an optimization rather than a requirement for correctness. The Daml model should be designed such that duplicated commands are either rejected (e.g. using keys or relying on changing contract IDs) or benign.

12.6.3.8 Authorization

When using Daml triggers against a Ledger with [request authorization](#), you can pass `--access-token-file token.jwt` to `daml trigger` which will read the token from the file `token.jwt`.

If you plan to run more than one trigger at a time, or triggers for more than one party at a time, you may be interested in the [Trigger Service \(Deprecated\)](#).

12.6.3.9 When Not to Use Daml Triggers

Daml triggers deliberately only allow you to express automation that listens for ledger events and reacts to them by sending commands to the ledger.

Daml Triggers are not suited for automation that needs to interact with services or data outside of the ledger. For those cases, you can write a ledger client using the [JavaScript bindings](#) running against the HTTP JSON API or the [Java bindings](#) running against the gRPC Ledger API.

12.6.3.10 Trigger Service (Deprecated)

The [Run a No-Op Trigger](#) section shows a simple method using the `daml trigger` command to arrange for the execution of a single trigger. Using this method, a dedicated process is launched to host the trigger.

Complex workflows can require running many triggers for many parties and at a certain point, use of `daml trigger` with its process-per-trigger model becomes unwieldy. The Trigger Service provides the means to host multiple triggers for multiple parties running against a common ledger in a single process and provides a convenient interface for starting, stopping and monitoring them.

The Trigger Service is a ledger client that acts as an end-user agent. The Trigger Service intermediates between the ledger and end-users by running triggers on their behalf. The Trigger Service is an HTTP service. All requests and responses use JSON to encode data.

Start the Trigger Service

In this example, it is assumed there is a Ledger API server running on port 6865 on *localhost*.

```
daml trigger-service --config trigger-service.conf
```

The following snippet provides an example of what a possible `trigger-service.conf` configuration file could look like, alongside a few annotations with regards to the meaning of the configuration keys and possibly their default values.

```
{
  // Paths to the DAR files containing the code executed by the trigger.
  dar-paths = [
    "./my-app.dar"
  ]

  // Host address that the Trigger Service listens on. Defaults to 127.0.0.1.
  address = "127.0.0.1"

  // Trigger Service port number. Defaults to 8088.
  // A port number of 0 will let the system pick an ephemeral port.
  port = 8088
  // Optional. If using 0 as the port number, consider specifying the path to a
  ➔ `port-file` where the chosen port will be saved in textual format.
  //port-file = "/path/to/port-file"

  // Mandatory. Ledger API server address and port.
  ledger-api {
    address = "localhost"
```

(continues on next page)

(continued from previous page)

```

    port = 6865
}

// Maximum inbound message size in bytes. Defaults to 4194304 (4 MB).
max-inbound-message-size = 4194304

// Minimum and maximum time interval before restarting a failed trigger.
↳ Defaults to 5 and 60 seconds respectively.
min-restart-interval = 5s
max-restart-interval = 60s

// Maximum HTTP entity upload size in bytes. Defaults to 4194304 (4 MB).
max-http-entity-upload-size = 4194304

// HTTP entity upload timeout. Defaults to 60 seconds.
http-entity-upload-timeout = 60s

// Use static or wall-clock time. Defaults to `wall-clock`.
time-provider-type = "wall-clock"

// Compiler configuration type to use between `default` or `dev`. Defaults to
↳ `default`.
compiler-config = "default"

// Time-to-live used for commands emitted by the trigger. Defaults to 30
↳ seconds.
ttl = 30s

// If true, initialize the database and terminate immediately. Defaults to
↳ false.
init-db = "false"

// Do not abort if there are existing tables in the database schema. EXPERT
↳ ONLY. Defaults to false.
allow-existing-schema = "false"

// Configuration of trigger runners.
trigger-config {
    // The number of ledger client command invocations each trigger will attempt
↳ to execute in parallel. Defaults to 8.
    parallelism = 8

    // Maximum number of retries for a failing ledger API command submission.
↳ Failed submission requests may be
    // handled by trigger rules. Defaults to 6.
    max-retries = 6

    // Used to control maximum rate at which we perform ledger client submission
↳ requests.
    max-submission-requests = 100 // Defaults to 100.
    max-submission-duration = 5s // Defaults to 5s.

    // Size of the queue holding ledger API command submission failures. When
↳ queue is filled, submission requests
    // are dropped. Defaults to 264.
    submission-failure-queue-size = 264

```

(continues on next page)

(continued from previous page)

```

}

// Configuration for the persistent store that will be used to keep track of
↳ running triggers across restarts.
// Mandatory if `init-db` is true. Otherwise optional. If not provided, the
↳ trigger state will not be persisted
// and restored across restarts.
trigger-store {

    // Mandatory. Database coordinates.
    user = "postgres"
    password = "password"
    driver = "org.postgresql.Driver"
    url = "jdbc:postgresql://localhost:5432/test?&ssl=true"

    // Prefix for table names to avoid collisions. EXPERT ONLY. By default, this
↳ is empty and not used.
    //table-prefix = "foo"

    // Maximum size for the database connection pool. Defaults to 8.
    pool-size = 8

    // Minimum idle connections for the database connection pool. Defaults to 8.
    min-idle = 8

    // Idle timeout for the database connection pool. Defaults to 10 seconds.
    idle-timeout = 10s

    // Timeout for database connection pool. Defaults to 5 seconds.
    connection-timeout = 5s
}

authorization {

    // Auth client to redirect to login. Defaults to `no`.
    auth-redirect = "no"

    // The following options configure the auth URIs.
    // Either just `auth-common-uri` or both `auth-internal-uri` and `auth-
↳ external-uri` must be specified.
    // If all are specified, `auth-internal-uri` and `auth-external-uri` take
↳ precedence.

    // Sets both the internal and external auth URIs.
    //auth-common-uri = "https://oauth2/common-uri"

    // Internal auth URI used by the Trigger Service to connect directly to the
↳ Auth Middleware.
    auth-internal-uri = "https://oauth2/internal-uri"

    // External auth URI (the one returned to the browser).
    // This value takes precedence over the one specified for `auth-common`.
    auth-external-uri = "https://oauth2/external-uri"

    // Optional. URI to the auth login flow callback endpoint `/cb`. By default
↳ it is constructed from the incoming login request.

```

(continues on next page)

(continued from previous page)

```
// auth-callback-uri = "https://oauth2/callback-uri"

// Maximum number of pending authorization requests. Defaults to 250.
max-pending-authorizations = 250

// Authorization timeout. Defaults to 60 seconds.
authorization-timeout = 60s
}

// Optional. Trigger service ledger API client TLS configuration. By default
// TLS configuration is disabled.
//tls-config {
//    enabled = "true"
//
//    // the certificate to be used by the server
//    cert-chain-file = "/path/to/ledger-api.crt"
//
//    // private key of the server
//    private-key-file = "/path/to/ledger-api.pem"
//
//    // trust collection, which means that all client certificates that will be
//    // verified using the trusted
//    // certificates in this store. If omitted, the JVM default trust store is
//    // used.
//    trust-collection-file = "/path/to/root-ca.crt"
//}
}
```

The Trigger Service can also be started using command line arguments as shown below. The command `daml trigger-service --help` lists all available parameters.

Note: Using the configuration format shown above is the recommended way to configure Trigger Service, running with command line arguments is now deprecated.

```
daml trigger-service --ledger-host localhost \
                    --ledger-port 6865 \
                    --wall-clock-time
```

Although, as we'll see, the Trigger Service exposes an endpoint for end-users to upload DAR files to the service it is sometimes convenient to start the service pre-configured with a specific DAR. To do this, the `--dar` option is provided.

```
daml trigger-service --ledger-host localhost \
                    --ledger-port 6865 \
                    --wall-clock-time \
                    --dar .daml/dist/create-daml-app-0.1.0.dar
```

Endpoints

Start a Trigger

Start a trigger. In this example, alice starts the trigger called trigger in a module called TestTrigger of a package with ID 312094804c1468e2166bae3c9ba8b5cc0d285e31356304a2e9b0ac549df59d14. The response contains an identifier for the running trigger that alice can use in subsequent commands involving the trigger.

HTTP Request

URL: /v1/triggers
Method: POST
Content-Type: application/json
Content:

```
{
  "triggerName":
  ↪ "312094804c1468e2166bae3c9ba8b5cc0d285e31356304a2e9b0ac549df59d14:TestTrigger:trigger
  ↪ ",
  "party": "alice",
  "applicationId": "my-app-id"
}
```

where

triggerName contains the identifier for the trigger in the form `${packageId}:${moduleName}:${identifierName}`. You can find the package ID using `daml damlc inspect path/to/trigger.dar | head -1`.

party is the party on behalf of which the trigger is running.

applicationId is an optional field to specify the application ID the trigger will use for command submissions. If omitted, the trigger will default to using its random UUID identifier returned in the start request as the application ID.

HTTP Response

```
{
  "result": {"triggerId": "4d539e9c-b962-4762-be71-40a5c97a47a6"},
  "status": 200
}
```

Stop a Trigger

Stop a running trigger. In this example, the request asks to stop the trigger started above.

HTTP Request

URL: /v1/triggers/:id
Method: DELETE
Content-Type: application/json
Content:

HTTP Response

Content-Type: application/json
Content:

```
{
  "result": {"triggerId": "4d539e9c-b962-4762-be71-40a5c97a47a6"},
  "status": 200
}
```

List Running Triggers

List the triggers running on behalf of a given party.

HTTP Request

URL: /v1/triggers?party=:party
Method: GET

HTTP Response

Content-Type: application/json
Content:

```
{
  "result": {"triggerIds": ["4d539e9c-b962-4762-be71-40a5c97a47a6"]},
  "status": 200
}
```

Status of a Trigger

This endpoint returns data about a trigger, including the party on behalf of which it is running, its identifier, and its current state (querying the active contract set, running, or stopped).

HTTP Request

URL: /v1/triggers/:id
Method: GET

HTTP Response

Content-Type: application/json
Content:

```
{
  "result": {
    "party": "Alice",
    "triggerId":
    ↪ "312094804c1468e2166bae3c9ba8b5cc0d285e31356304a2e9b0ac549df59d14:TestTrigger:trigger
    ↪ ",
    "status": "running"
  },
  "status": 200
}
```

Upload a New DAR

Upload a DAR containing one or more triggers. If successful, the DAR's main package ID will be in the response (the main package ID for a DAR can also be obtained using `daml damlc inspect path/to/dar | head -1`).

HTTP Request

URL: /v1/packages
Method: POST
Content-Type: multipart/form-data
Content:
dar=\$dar_content

HTTP Response

Content-Type: application/json
Content:

```
{
  "result": { "mainPackageId":
    ↪ "312094804c1468e2166bae3c9ba8b5cc0d285e31356304a2e9b0ac549df59d14" },
  "status": 200
}
```

Liveness Check

This can be used as a liveness probe, e.g., in Kubernetes.

HTTP Request

URL: /livez
Method: GET

HTTP Response

A status code of 200 indicates a successful liveness check.

Content-Type: application/json
Content:

```
{ "status": "pass" }
```

Readiness Check

This can be used as a readiness probe, e.g., in Kubernetes.

HTTP Request

URL: /readyz
Method: GET

HTTP Response

A status code of 200 indicates a successful readiness check.

Metrics

Enable and Configure Reporting

To enable metrics and configure reporting, you can use the below config block in application config:

```
metrics {  
  // Start a metrics reporter. Must be one of "console", "csv:///PATH",  
  → "graphite://HOST[:PORT]/[METRIC_PREFIX]", or "prometheus://HOST[:PORT]".  
  reporter = "prometheus://localhost:9000"  
  // Set metric reporting interval, examples: 1s, 30s, 1m, 1h  
  reporting-interval = 30s  
}
```

Reported Metrics

If a Prometheus metrics reporter is configured, the Trigger Service exposes the [common HTTP metrics](#) for all endpoints.

Authorization

The trigger service (deprecated) issues commands to the ledger that may require authorization through an access token. See [Ledger Authorization](#) for a description of authentication and authorization on Daml ledgers. How to obtain an access token is defined by the ledger operator. The trigger service interfaces with an [Auth Middleware](#) to obtain an access token in order to decouple it from the specific authentication and authorization mechanism used for a given ledger.

Enable Authorization

You can use the following command-line flags to configure the trigger service to interface with a given auth middleware.

- auth** The URI to the auth middleware. The auth middleware should be reachable under this URI from the client as well as the trigger service itself.
- auth-callback** The login workflow may require redirection to the callback endpoint of the trigger service. This flag configures the URI to the trigger service's `/cb` endpoint, it should be reachable from the client.

For example, use the following flags if the trigger service and the auth middleware are both running behind a reverse proxy.:

```
--auth https://example.com/auth
--auth-callback https://example.com/trigger/cb
```

Assuming that the auth middleware is available under `https://example.com/auth` and the trigger service is available under `https://example.com/trigger`.

Note that the trigger service must be able to share cookies with the auth middleware as described in the [Deployment notes](#).

Obtain Authorization

The trigger service will respond with 401 Unauthorized if a request requires authentication and authorization of the user. The trigger service can be configured to redirect to the `/login` endpoint via HTTP redirect (302 Found) using the command-line flag `-auth-redirect`. This can be useful for testing if the IAM does not require user input.

The 401 Unauthorized response will include a [WWW-Authenticate header](#) of the form:

```
WWW-Authenticate
  DamlAuthMiddleware realm=":claims",login=":login",auth=":auth"
```

where

- `claims` are the required [Daml Ledger Claims](#).
- `login` is the URL to initiate the login flow on the auth middleware.
- `auth` is the URL to check whether authorization has been granted.

The response will also include an entity with

```
Content-Type: application/json
Content:
```

```
{
  "realm": ":claims",
  "login": ":auth",
  "auth": ":login",
}
```

An application can direct the user to the login URL, wait until authorization has been granted, and repeat the original request once authorization has been granted. The auth URL can be used to poll until authorization has been granted. Alternatively, it can append a custom `redirect_url` parameter to the login URL and redirect to the resulting URL. Note that login with the IAM may require entering credentials into a web-form, i.e. the login URL should be opened in a web browser.

Example

This section describes how a web frontend can interact with the trigger service (deprecated) when authorization is required. Note, to avoid cross-origin requests and to enable sharing of cookies the web application and auth middleware should be exposed under the same domain, e.g. behind a shared reverse proxy.

Let's start with a request to the [list running triggers](#) endpoint.

```
const resp = await fetch("/trigger/v1/triggers?party=Alice");
if (resp.status >= 200 && resp.status < 300) {
  const result = await resp.json();
  // process result ...
} else if (resp.status === 401) {
  // handle Unauthorized ...
} else {
  // handle other error ...
}
```

If the request succeeds it decodes the JSON response body and continues processing the result, otherwise it checks if the request failed with 401 Unauthorized or another error. We will ignore the general error case and focus only on handling the Unauthorized response.

Login via Redirect

A simple solution is to redirect the browser to the login URL after adding a `redirect_url` parameter that points back to the current page.

```
const challenge = await resp.json();
var loginUrl = new URL(challenge.login);
loginUrl.searchParams.append("redirect_uri", window.location.href);
window.location.replace(loginUrl.href);
```

This code first decodes the JSON encoded authentication challenge included in the response body, then it extends the login URL with a `redirect_uri` parameter that points back to the current page, and redirects the browser to the login flow. The browser will be redirected to the original page after the login flow completed at which point authorization should have been granted and the original request should succeed.

Login via Popup

Another solution is to direct the user to the login page in a separate window, wait until authorization has been granted, and then retry the original request.

```
const challenge = await resp.json();
await popupLogin(challenge.login, challenge.auth);
// retry original request ...
```

The function `popupLogin` opens the login URL in a popup window and polls on the auth URL until authorization has been granted. It raises an error if the login window closes before authorization has been granted.

```
function popupLogin(login, auth) {
  return new Promise(function (resolve, reject) {
    var popup = window.open(login);
    var timer = setInterval(async function() {
      const closed = popup.closed;
      const resp = await fetch(auth);
      if (resp.status >= 200 && resp.status < 300) {
        // The user logged in
        clearInterval(timer);
        popup.close();
        resolve();
      } else if (closed) {
        // The popup is closed but we are not logged in.
        reject(new Error("Login failed"))
      }
    }, 1000);
  });
}
```

12.6.3.11 Auth Middleware

Daml ledgers only validate authorization tokens. The issuance of those tokens however is something defined by the participant operator and can vary significantly across deployments. This poses a challenge when developing applications that need to be able to acquire and refresh authorization tokens but don't want to tie themselves to any particular mechanism for token issuance. The Auth Middleware aims to address this problem by providing an API that decouples Daml applications from these details. The participant operator can provide an Auth Middleware that is suitable for their authentication and authorization mechanism. Daml includes an implementation of an Auth Middleware that supports [OAuth 2.0 Authorization Code Grant](#). If this implementation is not compatible with your mechanism for token issuance, you can implement your own Auth Middleware provided it conforms to the same API.

Features

The Auth Middleware is designed to fulfill the following goals:

- Be agnostic of the authentication and authorization protocol required by the identity and access management (IAM) system used by the participant operator.
- Allow fine grained access control via Daml ledger claims.
- Support token refresh for long running clients that should not require user interaction.

Auth Middleware API

An implementation of the Auth Middleware must provide the following API.

Obtain Access Token

The application contacts this endpoint to determine if the issuer of the request is authenticated and authorized to access the given claims. The application must forward any cookies that it itself received in the original request. The response will contain an access token and optionally a refresh token if the issuer of the request is authenticated and authorized. Otherwise, the response will be 401 Unauthorized.

HTTP Request

URL: `/auth?claims=:claims`
Method: GET
Headers: Cookie

where

`claims` are the requested [Daml Ledger Claims](#).

For example:

```
/auth?claims=actAs:Alice+applicationId:MyApp
```

Note: When using user management, the participant operator may have configured their IAM to issue user tokens. The Auth Middleware currently doesn't accept an input parameter specific to user IDs. As such, it is up to the IAM to map claims request to the required user token. Our recommendation to participant operators is to map the `applicationId` claim to the required user ID. Application developers should contact their ledger operator to understand how they are supposed to request for a token.

HTTP Response

```
{  
  "access_token": "...",  
  "refresh_token": "..."  
}
```

where

`access_token` is the access token to use for Daml ledger commands.
`refresh_token` (optional) can be used to refresh an expired access token on the `/refresh` endpoint.

Request Authorization

The application directs the user to this endpoint if the `/auth` endpoint returned 401 Unauthorized. This will request authentication and authorization of the user from the IAM for the given claims. E.g. in the OAuth 2.0 based implementation included in Daml, this will start an Authorization Code Grant flow.

If authorization is granted this will store the access and optional refresh token in a cookie. The request can define a callback URI, if specified this endpoint will redirect to the callback URI at the end of the flow. Otherwise, it will respond with a status code that indicates whether authorization was successful or not.

HTTP Request

```
URL: /login?claims=:claims&redirect_uri=:redirect_uri&state=:state
Method: GET
```

where

`claims` are the requested [Daml Ledger Claims](#).
`redirect_uri` (optional) redirect to this URI at the end of the flow. Passes `error` and optionally `error_description` parameters if authorization failed.
`state` (optional) forward this parameter to the `redirect_uri` if specified.

For example:

```
/login?claims=actAs:Alice+applicationId:MyApp&redirect_uri=http://example.com/cb&
state=2b56cc2e-01ad-4e51-a9b3-124d4bbe0a91
```

Refresh Access Token

The application contacts this endpoint to refresh an expired access token without requiring user input. Token refresh is available if the `/auth` endpoint return a refresh token along side the access token. This endpoint will return a new access token and optionally a new refresh token to replace the old.

HTTP Request

```
URL: /refresh
Method: POST
Content-Type: application/json
Content:
```

```
{
  "refresh_token": "...
}
```

where

`refresh_token` is the refresh token returned by `/auth` or a previous `/refresh` request.

HTTP Response

```
{
  "access_token": "...",
  "refresh_token": "...",
}
```

where

`access_token` is the access token to use for Daml ledger commands.

`refresh_token` (optional) can be used to refresh an expired access token on the `/refresh` endpoint.

Daml Ledger Claims

A list of claims specifies the set of capabilities that are requested. These are passed as a URL-encoded, space-separated list of individual claims of the following form:

admin Access to admin-level services.

readAs:<Party Name> Read access for the given party.

actAs:<Party Name> Issue commands on behalf of the given party.

applicationId:<Application Id> Restrict access to commands issued with the given application ID.

See [Access Tokens and Claims](#) for further information on Daml ledger capabilities.

12.6.3.12 OAuth 2.0 Auth Middleware

Daml includes an implementation of an auth middleware that supports [OAuth 2.0 Authorization Code Grant](#). The implementation aims to be configurable to support different OAuth 2.0 providers and to allow custom mappings from Daml ledger claims to OAuth 2.0 scopes.

OAuth 2.0 Configuration

[RFC 6749](#) specifies that OAuth 2.0 providers offer two endpoints: The [authorization endpoint](#) and the [token endpoint](#). The URIs for these endpoints can be configured independently using the following fields:

```
oauth-auth
oauth-token
```

The OAuth 2.0 provider may require that the application identify itself using a client identifier and client secret. These can be specified using the following environment variables:

```
DAML_CLIENT_ID
DAML_CLIENT_SECRET
```

The auth middleware assumes that the OAuth 2.0 provider issues JWT access tokens. The `/auth` endpoint will validate the token, if available, and ensure that it grants the requested claims. The auth middleware accepts the same command-line flags as the [Daml Sandbox](#) to define the public key for token validation.

Request Templates

The exact format of OAuth 2.0 requests may vary between providers. Furthermore, the mapping from Daml ledger claims to OAuth 2.0 scopes is defined by the IAM operator. For that reason OAuth 2.0 requests made by auth middleware can be configured using user defined [Jsonnet](#) templates. Templates are parameterized configurations expressed as top-level functions.

Authorization Request

This template defines the format of the [Authorization request](#). Use the following config field to use a custom template:

```
oauth-auth-template
```

Arguments

The template will be passed the following arguments:

- config (object)**
 - `clientId` (string) the OAuth 2.0 client identifier
 - `clientSecret` (string) the OAuth 2.0 client secret
- request (object)**
 - **claims (object) the requested claims**
 - * `admin` (bool)
 - * `applicationId` (string or null)
 - * `actAs` (list of string)
 - * `readAs` (list of string)
 - `redirectUri` (string)
 - `state` (string)

Returns

The query parameters for the authorization endpoint encoded as an object with string values.

Example

```
local scope(claims) =
  local admin = if claims.admin then "admin";
  local applicationId = if claims.applicationId != null then "applicationId:" +
  →claims.applicationId;
  local actAs = std.map(function(p) "actAs:" + p, claims.actAs);
  local readAs = std.map(function(p) "readAs:" + p, claims.readAs);
  [admin, applicationId] + actAs + readAs;

function(config, request) {
  "audience": "https://daml.com/ledger-api",
  "client_id": config.clientId,
  "redirect_uri": request.redirectUri,
```

(continues on next page)

(continued from previous page)

```
"response_type": "code",
"scope": std.join(" ", ["offline_access"] + scope(request.claims)),
"state": request.state,
}
```

Token Request

This template defines the format of the [Token request](#). Use the following config field to use a custom template:

```
oauth-token-template
```

Arguments

The template will be passed the following arguments:

config (object)

- `clientId` (string) the OAuth 2.0 client identifier
- `clientSecret` (string) the OAuth 2.0 client secret

request (object)

- `code` (string)
- `redirectUri` (string)

Returns

The request parameters for the token endpoint encoded as an object with string values.

Example

```
function(config, request) {
  "client_id": config.clientId,
  "client_secret": config.clientSecret,
  "code": request.code,
  "grant_type": "authorization_code",
  "redirect_uri": request.redirectUri,
}
```

Refresh Request

This template defines the format of the [Refresh request](#). Use the following config field to use a custom template:

```
oauth-refresh-template
```

Arguments

The template will be passed the following arguments:

config (object)

- `clientId` (string) the OAuth 2.0 client identifier
- `clientSecret` (string) the OAuth 2.0 client secret

request (object)

- `refreshToken` (string)

Returns

The request parameters for the authorization endpoint encoded as an object with string values.

Example

```
function(config, request) {
  "client_id": config.clientId,
  "client_secret": config.clientSecret,
  "grant_type": "refresh_code",
  "refresh_token": request.refreshToken,
}
```

Deployment Notes

The auth middleware API relies on sharing cookies between the auth middleware and the Daml application. One way to enable this is to expose the auth middleware and the Daml application under the same domain, e.g. through a reverse proxy. Note that you will need to specify the external callback URI in that case using the `--callback` command-line flag.

For example, assuming the following nginx configuration snippet:

```
http {
  server {
    server_name example.com
    location /auth/ {
      proxy_pass http://localhost:3000/;
    }
  }
}
```

You would invoke the OAuth 2.0 auth middleware with the following flags:

```
oauth2-middleware \
  --config oauth-middleware.conf
```

The required config would look like

```
{
  // Environment variables:
```

(continues on next page)

(continued from previous page)

```

// DAML_CLIENT_ID      The OAuth2 client-id - must not be empty
// DAML_CLIENT_SECRET  The OAuth2 client-secret - must not be empty
client-id = ${DAML_CLIENT_ID}
client-secret = ${DAML_CLIENT_SECRET}

//IP address that OAuth2 Middleware service listens on. Defaults to 127.0.0.1.
address = "127.0.0.1"
//OAuth2 Middleware service port number. Defaults to 3000. A port number of 0
↳will let the system pick an ephemeral port. Consider specifying `--port-file`
↳option with port number 0.
port = 3000

//URI to the auth middleware's callback endpoint `/cb`. By default constructed
↳from the incoming login request.
callback-uri = "https://example.com/auth/cb"

//Maximum number of simultaneously pending login requests. Requests will be
↳denied when exceeded until earlier requests have been completed or timed out.
max-login-requests = 250

//Login request timeout. Requests will be evicted if the callback endpoint
↳receives no corresponding request in time.
login-timeout = 60s

//Enable the Secure attribute on the cookie that stores the token. Defaults to
↳true. Only disable this for testing and development purposes.
cookie-secure = "true"

//URI of the OAuth2 authorization endpoint
oauth-auth="https://oauth2-provider.com/auth_uri"

//URI of the OAuth2 token endpoint
oauth-token="https://oauth2-provider.com/token_uri"

//OAuth2 authorization request Jsonnet template
oauth-auth-template="file://path/oauth/auth/template"

//OAuth2 token request Jsonnet template
oauth-token-template = "file://path/oauth/token/template"

//OAuth2 refresh request Jsonnet template
oauth-refresh-template = "file://path/oauth/refresh/template"

// Enables JWT-based authorization, where the JWT is signed by one of the below
↳Jwt based token verifiers
token-verifier {
  // type can be rs256-crt, es256-crt, es512-crt or rs256-jwks
  type = "rs256-jwks"
  // X509 certificate file (.crt)/JWKS url from where the public key is loaded
  uri = "https://example.com/.well-known/jwks.json"
}
}

```

The oauth2-middleware can also be started using cli-args.

Note: Configuration file is the recommended way to run oauth2-middleware, running via cli-args is

now deprecated

```
oauth2-middleware \
  --callback https://example.com/auth/cb \
  --address localhost \
  --http-port 3000 \
  --oauth-auth https://oauth2-provider.com/auth_uri \
  --oauth-token https://oauth2-provider.com/token_uri \
  --auth-jwt-rs256-jwks https://example.com/.well-known/jwks.json
```

Some browsers reject Secure cookies on unencrypted connections even on localhost. You can pass the command-line flag `--cookie-secure no` for testing and development on localhost to avoid this.

Metrics

You may configure the `oauth2-middleware` to expose the [common HTTP metrics](#) via a Prometheus reporter by adding the below section to the application config:

```
metrics {
  // Start a metrics reporter. Must be one of "console", "csv:///PATH",
  ↪ "graphite://HOST[:PORT][METRIC_PREFIX]", or "prometheus://HOST[:PORT]".
  reporter = "prometheus://localhost:9000"
  // Set metric reporting interval , examples : 1s, 30s, 1m, 1h
  reporting-interval = 30s
}
```

Liveness and Readiness Endpoints

The following sections describe the endpoints that can be used to probe the liveness and readiness of the auth middleware service.

Liveness Check

This can be used as a liveness probe, e.g., in Kubernetes.

HTTP Request

URL: `/livez`
Method: GET

HTTP Response

A status code of 200 indicates a successful liveness check.

Content-Type: application/json

Content:

```
{ "status": "pass" }
```

Readiness Check

This can be used as a readiness probe, e.g., in Kubernetes.

HTTP Request

URL: /readyz

Method: GET

HTTP Response

A status code of 200 indicates a successful readiness check.

12.7 Handle Errors

12.7.1 Command Deduplication

The interaction of a Daml application with the ledger is inherently asynchronous: applications send commands to the ledger, and some time later they see the effect of that command on the ledger. Many things can fail during this time window:

- The application can crash.

- The participant node can crash.

- Messages can be lost on the network.

- The ledger may be slow to respond due to a high load.

If you want to make sure that an intended ledger change is not executed twice, your application needs to robustly handle all failure scenarios. This guide covers the following topics:

- [How command deduplication works.](#)

- [How applications can effectively use the command deduplication.](#)

12.7.1.1 How Command Deduplication Works

The following fields in a command submissions are relevant for command deduplication. The first three form the *change ID* that identifies the intended ledger change.

The union of *party* and *act_as* define the submitting parties.

The *application ID* identifies the application that submits the command.

The *command ID* is chosen by the application to identify the intended ledger change.

The deduplication period specifies the period for which no earlier submissions with the same change ID should have been accepted, as witnessed by a completion event on the *command completion service*. If such a change has been accepted in that period, the current submission shall be rejected. The period is specified either as a *deduplication duration* or as a *deduplication offset* (inclusive).

The *submission ID* is chosen by the application to identify a specific submission. It is included in the corresponding completion event so that the application can correlate specific submissions to specific completions. An application should never reuse a submission ID.

The ledger may arbitrarily extend the deduplication period specified in the submission, even beyond the maximum deduplication duration specified in the *ledger configuration*.

Note: The maximum deduplication duration is the length of the deduplication period guaranteed to be supported by the participant.

The deduplication period chosen by the ledger is the *effective deduplication period*. The ledger may also convert a requested deduplication duration into an effective deduplication offset or vice versa. The effective deduplication period is reported in the command completion event in the *deduplication duration* or *deduplication offset* fields.

A command submission is considered a **duplicate submission** if at least one of the following holds:

The submitting participant's completion service contains a successful completion event for the same *change ID* within the *effective deduplication period*.

The participant or Daml ledger are aware of another command submission in-flight with the same *change ID* when they perform command deduplication.

The outcome of command deduplication is communicated as follows:

Command submissions via the *command service* indicate the command deduplication outcome as a synchronous gRPC response unless the *gRPC deadline* was exceeded.

Note: The outcome MAY additionally appear as a completion event on the *command completion service*, but applications using the *command service* typically need not process completion events.

Command submissions via the *command submission service* can indicate the outcome as a synchronous gRPC response, or asynchronously through the *command completion service*. In particular, the submission may be a duplicate even if the command submission service acknowledges the submission with the gRPC status code OK.

Independently of how the outcome is communicated, command deduplication generates the following outcomes of a command submission:

If there is no conflicting submission with the same *change ID* on the Daml ledger or in-flight, the completion event and possibly the response convey the result of the submission (success

or a gRPC error; [Error Codes](#) explains how errors are communicated).

The gRPC status code `ALREADY_EXISTS` with error code ID `DUPLICATE_COMMAND` indicates that there is an earlier command completion for the same [change ID](#) within the effective deduplication period.

The gRPC status code `ABORTED` with error code id `SUBMISSION_ALREADY_IN_FLIGHT` indicates that another submission for the same [change ID](#) was in flight when this submission was processed.

The gRPC status code `FAILED_PRECONDITION` with error code id `INVALID_DEDUPPLICATION_PERIOD` indicates that the specified deduplication period is not supported. The fields `longest_duration` or `earliest_offset` in the metadata specify the longest duration or earliest offset that is currently supported on the Ledger API endpoint. At least one of the two fields is present.

Neither deduplication durations up to the [maximum deduplication duration](#) nor deduplication offsets published within that duration SHOULD result in this error. Participants may accept longer periods at their discretion.

The gRPC status code `FAILED_PRECONDITION` with error code id `PARTICIPANT_PRUNED_DATA_ACCESSED`, when specifying a deduplication period represented by an offset, indicates that the specified deduplication offset has been pruned. The field `earliest_offset` in the metadata specifies the last pruned offset.

For deduplication to work as intended, all submissions for the same ledger change must be submitted via the same participant. Whether a submission is considered a duplicate is determined by completion events, and by default a participant outputs only the completion events for submissions that were requested via the very same participant.

12.7.1.2 How to Use Command Deduplication

To effectuate a ledger change exactly once, the application must resubmit a command if an earlier submission was lost. However, the application typically cannot distinguish a lost submission from slow submission processing by the ledger. Command deduplication allows the application to resubmit the command until it is executed and reject all duplicate submissions thereafter.

Some ledger changes can be executed at most once, so no command deduplication is needed for them. For example, if the submitted command exercises a consuming choice on a given contract ID, this command can be accepted at most once because every contract can be archived at most once. All duplicate submissions of such a change will be rejected with `CONTRACT_NOT_ACTIVE`.

In contrast, a [Create command](#) would create a fresh contract instance of the given [template](#) for each submission that reaches the ledger (unless other constraints such as the [template preconditions](#) or contract key uniqueness are violated). Similarly, an [Exercise command](#) on a non-consuming choice or an [Exercise-By-Key command](#) may be executed multiple times if submitted multiple times. With command deduplication, applications can ensure such intended ledger changes are executed only once within the deduplication period, even if the application resubmits, say because it considers the earlier submissions to be lost or forgot during a crash that it had already submitted the command.

Known Processing Time Bounds

For this strategy, you must estimate a bound B on the processing time and forward clock drifts in the Daml ledger with respect to the application's clock. If processing measured across all retries takes longer than your estimate B , the ledger change may take effect several times. Under this caveat, the following strategy works for applications that use the [Command Service](#) or the [Command Submission](#) and [Command Completion Service](#).

Note: The bound B should be at most the configured [maximum deduplication duration](#). Otherwise you rely on the ledger accepting longer deduplication durations. Such reliance makes your application harder to port to other Daml ledgers and fragile, as the ledger may stop accepting such extended durations at its own discretion.

1. Choose a command ID for the ledger change, in a way that makes sure the same ledger change is always assigned the same command ID. Either determine the command ID deterministically (e.g., if your contract payload contains a globally unique identifier, you can use that as your command ID), or choose the command ID randomly and persist it with the ledger change so that the application can use the same command ID in resubmissions after a crash and restart.

Note: Make sure that you assign the same command ID to all command (re-)submissions of the same ledger change. This is useful for the recovery procedure after an application crash/restart. After a crash, the application in general cannot know whether it has submitted a set of commands before the crash. If in doubt, resubmit the commands using the same command ID. If the commands had been submitted before the crash, command deduplication on the ledger will reject the resubmissions.

2. When you use the [Command Completion Service](#), obtain a recent offset on the completion stream `OFF1`, say the [current ledger end](#).
3. Submit the command with the following parameters:
 - Set the [command ID](#) to the chosen command ID from [Step 1](#).
 - Set the [deduplication duration](#) to the bound B .

Note: It is prudent to explicitly set the deduplication duration to the desired bound B , to guard against the case where a ledger configuration update shortens the maximum deduplication duration. With the bound B , you will be notified of such a problem via an [INVALID_DEDUPLICATION_PERIOD](#) error if the ledger does not support deduplication durations of length B any more.

If you omitted the deduplication period, the currently valid maximum deduplication duration would be used. In this case, a ledger configuration update could silently shorten the deduplication period and thus invalidate your deduplication analysis.

Set the [submission ID](#) to a fresh value, e.g., a random UUID.

Set the timeout (gRPC deadline) to the expected submission processing time (Command Service) or submission hand-off time (Command Submission Service).

The **submission processing time** is the time between when the application sends off a submission to the [Command Service](#) and when it receives (synchronously, unless it times out) the acceptance or rejection. The **submission hand-off time** is the time between when the application sends off a submission to the [Command Submission Service](#) and when it obtains a synchronous response for this gRPC call. After the RPC timeout, the application considers the submission as lost and enters a retry loop. This timeout is typically much

shorter than the deduplication duration.

4. Wait until the RPC call returns a response.

Status codes other than OK should be handled according to [error handling](#).

When you use the [Command Service](#) and the response carries the status code OK, the ledger change took place. You can report success.

When you use the [Command Submission Service](#), subscribe with the [Command Completion Service](#) for completions for actAs from OFF1 (exclusive) until you see a completion event for the change ID and the submission ID chosen in [Step 3](#). If the completion's status is OK, the ledger change took place and you can report success. Other status codes should be handled according to [error handling](#).

This step needs no timeout as the [Command Submission Service](#) acknowledges a submission only if there will eventually be a completion event, unless relevant parts of the system become permanently unavailable.

Error Handling

Error handling is needed when the status code of the command submission RPC call or in the [completion event](#) is not OK. The following table lists appropriate reactions by status code (written as STATUS_CODE) and error code (written in capital letters with a link to the error code documentation). Fields in the error metadata are written as field in lowercase letters.

Table 1: Command deduplication error handling with known processing time bound

Error condition	Reaction
DEAD-LINE_EXCEEDED	Consider the submission lost. Retry from Step 2 , obtaining the completion offset <code>OFF1</code> , and possibly increase the timeout.
Application crashed	Retry from Step 2 , obtaining the completion offset <code>OFF1</code> .
ALREADY_EXISTS / DUPLICATE_COMMAND	The change ID has already been accepted by the ledger within the reported deduplication period. The optional field <code>completion_offset</code> contains the precise offset. The optional field <code>existing_submission_id</code> contains the submission ID of the successful submission. Report success for the ledger change.
FAILED_PRECONDITION / INVALID_DEDUPPLICATION_PERIOD	The specified deduplication period is longer than what the Daml ledger supports or the ledger cannot handle the specified deduplication offset. <code>earliest_offset</code> contains the earliest deduplication offset or <code>longest_duration</code> contains the longest deduplication duration that can be used (at least one of the two must be provided). Options: Negotiate support for longer deduplication periods with the ledger operator. Set the deduplication offset to <code>earliest_offset</code> or the deduplication duration to <code>longest_duration</code> and retry from Step 2 , obtaining the completion offset <code>OFF1</code> . This may lead to accepting the change twice within the originally intended deduplication period.
FAILED_PRECONDITION / PARTICIPANT_PRUNED_DATA_ACCEPTED	The specified deduplication offset has been pruned by the participant. <code>earliest_offset</code> contains the last pruned offset. Use the Command Completion Service by asking for the completions , starting from the last pruned offset by setting <code>offset</code> to the value of <code>earliest_offset</code> , and use the first received <code>offset</code> as a deduplication offset.
ABORTED / SUBMISSION_ALREADY_IN_FLIGHT This error occurs only as an RPC response, not inside a completion event.	There is already another submission in flight, with the submission ID in <code>existing_submission_id</code> . When you use the Command Service , wait a bit and retry from Step 3 , submitting the command. Since the in-flight submission might still be rejected, (repeated) resubmission ensures that you (eventually) learn the outcome: If an earlier submission was accepted, you will eventually receive a DUPLICATE_COMMAND rejection. Otherwise, you have a second chance to get the ledger change accepted on the ledger and learn the outcome. When you use the Command Completion Service , look for a completion for <code>existing_submission_id</code> instead of the chosen submission ID in Step 4 .
ABORTED / other error codes	Wait a bit and retry from Step 2 , obtaining the completion offset <code>OFF1</code> .
other error conditions	Use background knowledge about the business workflow and the current ledger state to decide whether earlier submissions might still get accepted. If you conclude that it cannot be accepted any more, stop retrying and report that the ledger change failed.
12.7. Handle Errors	Otherwise, retry from Step 2 , obtaining a completion offset <code>OFF1</code> , or give up without knowing for sure that the ledger change will not happen. For example, if the ledger change only creates a contract instance of a template, you can never be sure, as any outstanding submission might still be accepted

Failure Scenarios

The above strategy can fail in the following scenarios:

1. The bound `B` is too low: The command can be executed multiple times.
Possible causes:
You have retried for longer than the deduplication duration, but never got a meaningful answer, e.g., because the timeout (gRPC deadline) is too short. For example, this can happen due to long-running Daml interpretation when using the [Command Service](#).
The application clock drifts significantly from the participant's or ledger's clock.
There are unexpected network delays.
Submissions are retried internally in the participant or Daml ledger and those retries do not stop before `B` is over. Refer to the specific ledger's documentation for more information.
2. Unacceptable changes cause infinite retries
You need business workflow knowledge to decide that retrying does not make sense any more. Of course, you can always stop retrying and accept that you do not know the outcome for sure.

Unknown Processing Time Bounds

Finding a good bound `B` on the processing time is hard, and there may still be unforeseen circumstances that delay processing beyond the chosen bound `B`. You can avoid these problems by using deduplication offsets instead of durations. An offset defines a point in the history of the ledger and is thus not affected by clock skews and network delays. Offsets are arguably less intuitive and require more effort by the application developer. We recommend the following strategy for using deduplication offsets:

1. Choose a fresh command ID for the ledger change and the `actAs` parties, which (together with the application ID) determine the change ID. Remember the command ID across application crashes. (Analogous to [Step 1 above](#))
2. Obtain a recent offset `OFF0` on the completion event stream and remember across crashes that you use `OFF0` with the chosen command ID. There are several ways to do so:
Use the [Command Completion Service](#) by asking for the [current ledger end](#).

Note: Some ledger implementations reject deduplication offsets that do not identify a command completion visible to the submitting parties with the error code `INVALID_DEDUPLICATION_PERIOD`. In general, the ledger end need not identify a command completion that is visible to the submitting parties. When running on such a ledger, use the Command Service approach described next.

Use the [Command Service](#) to obtain a recent offset by repeatedly submitting a dummy command, e.g., a [Create-And-Exercise command](#) of some single-signatory template with the [Archive](#) choice, until you get a successful response. The response contains the [completion offset](#).

3. When you use the [Command Completion Service](#):
If you execute this step the first time, set `OFF1 = OFF0`.
If you execute this step as part of [error handling](#) retrying from Step 3, obtaining the completion offset `OFF1`, obtain a recent offset on the completion stream `OFF1`, say its current end. (Analogous to [step 2 above](#))
4. Submit the command with the following parameters (analogous to [Step 3 above](#) except for the deduplication period):

Set the [command ID](#) to the chosen command ID from [Step 1](#).

Set the [deduplication offset](#) to `OFF0`.

Set the [submission ID](#) to a fresh value, e.g., a random UUID.

Set the timeout (gRPC deadline) to the expected submission processing time (Command Service) or submission hand-off time (Command Submission Service).

5. Wait until the RPC call returns a response.

Status codes other than `OK` should be handled according to [error handling](#).

When you use the [Command Service](#) and the response carries the status code `OK`, the ledger change took place. You can report success. The response contains a [completion offset](#) that you can use in [Step 2](#) of later submissions.

When you use the [Command Submission Service](#), subscribe with the [Command Completion Service](#) for completions for `actAs` from `OFF1` (exclusive) until you see a completion event for the change ID and the submission ID chosen in [step 3](#). If the completion's status is `OK`, the ledger change took place and you can report success. Other status codes should be handled according to [error handling](#).

Error Handling

The same as [for known bounds](#), except that the former retry from [Step 2](#) becomes retry from [Step 3](#).

Failure Scenarios

The above strategy can fail in the following scenarios:

1. No success within the supported deduplication period
When the application receives a [INVALID_DEDUPLICATION_PERIOD](#) error, it cannot achieve exactly once execution any more within the originally intended deduplication period.
2. Unacceptable changes cause infinite retries
You need business workflow knowledge to decide that retrying does not make sense any more. Of course, you can always stop retrying and accept that you do not know the outcome for sure.

12.8 Authorization

When developing Daml applications using SDK tools, your local setup will most likely not perform any Ledger API request authorization – by default, any valid Ledger API request will be accepted by the sandbox.

This is not the case for participant nodes of deployed ledgers. For every Ledger API request, the participant node checks whether the request contains an access token that is valid and sufficient to authorize that request. You thus need to add support for authorization using access tokens to your application to run it against a deployed ledger.

Note: In case of mutual (two-way) TLS authentication, the Ledger API client must present its certificate (in addition to an access token) to the Ledger API server as part of the authentication process. The provided certificate must be signed by a certificate authority (CA) trusted by the Ledger API server. Note that the identity of the application will not be proven by using this method, i.e. the `application_id` field in the request is not necessarily correlated with the CN (Common Name) in the certificate.

12.8.1 Introduction

Your Daml application sends requests to the [Ledger API](#) exposed by a participant node to submit changes to the ledger (e.g., *exercise choice X on contract Y as party Alice*), or to read data from the ledger (e.g., *read all active contracts visible to party Alice*). Your application might send these requests via a middleware like the [JSON API](#).

Whether a participant node *can* serve such a request depends on whether the participant node hosts the respective parties, and whether the request is valid according to the [Daml Ledger Model](#). Whether a participant node *will* serve such a request to a Daml application depends on whether the request includes an access token that is valid and sufficient to authorize the request for this participant node.

12.8.2 Acquire and Use Access Tokens

How an application acquires access tokens depends on the participant node it talks to and is ultimately set up by the participant node operator. Many setups use a flow in the style of [OAuth 2.0](#).

In this scenario, the Daml application first contacts a token issuer to get an access token. The token issuer verifies the identity of the requesting application, looks up the privileges of the application, and generates a signed access token describing those privileges.

Once the access token is issued, the Daml application sends it along with every Ledger API request. The Daml ledger verifies:

- that the token was issued by one of its trusted token issuers
- that the token has not been tampered with
- that the token had not expired
- that the privileges described in the token authorize the request

How you attach tokens to requests depends on the tool or library you use to interact with the Ledger API. See the tool's or library's documentation for more information. (E.g. relevant documentation for the [Java bindings](#) and the [JSON API](#).)

12.8.3 Access Tokens and Rights

Access tokens contain information about the rights granted to the bearer of the token. These rights are specific to the API being accessed.

The Daml Ledger API uses the following rights to govern request authorization:

- `public`: the right to retrieve publicly available information, such as the ledger identity
- `participant_admin`: the right to administer the participant node
- `idp_admin`: the right to administer the users and parties belonging the same identity provider configuration as the authenticated user
- `canReadAs (p)`: the right to read information off the ledger (like the active contracts) visible to the party `p`
- `canActsAs (p)`: same as `canReadAs (p)`, with the added right of issuing commands on behalf of the party `p`

The following table summarizes the rights required to access each Ledger API endpoint:

Ledger API service	Endpoint	Required right
LedgerIdentityService	GetLedgerIdentity	public
ActiveContractsService	GetActiveContracts	for each requested party p: canReadAs(p)
CommandCompletionService	CompletionEnd	public
	CompletionStream	for each requested party p: canReadAs(p)
CommandSubmissionService	Submit	for submitting party p: canActAs(p)
CommandService	All	for submitting party p: canActAs(p)
EventQueryService	All	for each requesting party p: canReadAs(p)
Health	All	no access token required for health checking
IdentityProviderConfigService	All	participant_admin
LedgerConfigurationService	GetLedgerConfiguration	public
MeteringReportService	All	participant_admin
PackageService	All	public
PackageManagementService	All	participant_admin
PartyManagementService	All	participant_admin
	All (except GetParticipantId, UpdatePartyIdentityProviderId)	idp_admin
ParticipantPruningService	All	participant_admin
ServerReflection	All	no access token required for gRPC service reflection
TimeService	GetTime	public
	SetTime	participant_admin
TransactionService	LedgerEnd	public
	All (except LedgerEnd)	for each requested party p: canReadAs(p)
UserManagementService	All	participant_admin
	All (except UpdateUserIdentityProviderId)	idp_admin
	GetUser	authenticated users can get their own user
	ListUserRights	authenticated users can list their own rights
VersionService	All	public

12.8.4 Access Token Formats

Applications should treat access tokens as opaque blobs. However, as an application developer it can be helpful to understand the format of access tokens to debug problems.

All Daml ledgers represent access tokens as [JSON Web Tokens \(JWTs\)](#), and there are two formats of the JSON payload used by Daml ledgers.

Note: To generate access tokens for testing purposes, you can use the jwt.io web site.

12.8.4.1 User Access Tokens

Daml ledgers that support participant [user management](#) also accept user access tokens. They are useful for scenarios where an application's rights change dynamically over the application's lifetime.

User access tokens do not encode rights directly like the custom Daml claims tokens explained in the following sections. Instead, user access tokens encode the participant user on whose behalf the request is issued.

When handling such requests, participant nodes look up the participant user's current rights before checking request authorization per the [table above](#). Thus the rights granted to an application can be changed dynamically using the participant user management service *without* issuing new access tokens, as would be required for the custom Daml claims tokens.

User access tokens are [JWTs](#) that follow the [OAuth 2.0 standard](#). There are two different JSON encodings: An audience-based token format that relies on the audience field to specify that it is designated for a specific Daml participant and a scope-based audience token format which relies on the scope field to designate the purpose. Both formats can be used interchangeably but if possible, use of the audience-based token format is recommend as it is compatible with a wider range of IAMs, e.g., Kubernetes does not support setting the scope field and makes the participant id mandatory which prevents misuse of a token on a different participant.

Audience-Based Tokens

```
{
  "aud": "https://daml.com/jwt/aud/participant/someParticipantId",
  "sub": "someUserId",
  "iss": "someIdpId",
  "exp": 1300819380
}
```

To interpret the above notation:

- aud is a required field which restricts the token to participant nodes with the given ID (e.g. someParticipantId)
- sub is a required field which specifies the participant user's ID
- iss is a field which specifies the identity provider id
- exp is an optional field which specifies the JWT expiration date (in seconds since EPOCH)

Scope-Based Tokens

```
{
  "aud": "someParticipantId",
  "sub": "someUserId",
  "exp": 1300819380,
  "iss": "someIdpId",
  "scope": "daml_ledger_api"
}
```

To interpret the above notation:

- `aud` is an optional field which restricts the token to participant nodes with the given ID
- `sub` is a required field which specifies the participant user's ID
- `iss` is a field which specifies the identity provider id
- `exp` is an optional field which specifies the JWT expiration date (in seconds since EPOCH)
- `scope` is a space-separated list of [OAuth 2.0 scopes](#) that must contain the `"daml_ledger_api"` scope

Requirements for User IDs

User IDs must be non-empty strings of at most 128 characters that are either alphanumeric ASCII characters or one of the symbols `@^$.!~-#+~_|: .`

Identity providers

An identity provider configuration can be thought of as a set of participant users which:

- Have a defined way to verify their access tokens
- Can be administered in isolation from the rest of the users on the same participant node
- Have an identity provider id unique per participant node
- Have a related set of parties that share the same identity provider id

A participant node always has a statically configured default identity provider configuration whose id is the empty string `""`. Additionally, you can configure a small number of non-default identity providers using `IdentityProviderConfigService` by supplying a non-empty identity provider id and a [JWK Set](#) URL which the participant node will use to retrieve the cryptographic data needed to verify the access tokens.

When authenticating as a user from a non-default identity provider configuration, your access tokens must contain the `iss` field whose value matches the identity provider id. In case of the default identity provider configuration, the `iss` field can be empty or omitted from the access tokens.

12.8.4.2 Custom Daml Claims Access Tokens

This format represents the *rights* granted by the access token as custom claims in the JWT's payload, like so:

```
{
  "https://daml.com/ledger-api": {
    "ledgerId": null,
    "participantId": "123e4567-e89b-12d3-a456-426614174000",
    "applicationId": null,
    "admin": true,
    "actAs": ["Alice"],
    "readAs": ["Bob"]
  },
  "exp": 1300819380
}
```

where all of the fields are optional, and if present,

- ledgerId and participantId restrict the validity of the token to the given ledger or participant node
- applicationId requires requests with this token to use that application id or not set an application id at all, which should be used to distinguish requests from different applications
- exp is the standard JWT expiration date (in seconds since EPOCH)
- actAs, readAs and (participant) admin encode the rights granted by this access token

The public right is implicitly granted to any request bearing a non-expired JWT issued by a trusted issuer with matching ledgerId, participantId and applicationId values.

Note: All Daml ledgers also support a deprecated legacy format of custom Daml claims access tokens whose format is equal to the above except that the custom claims are present at the same level as exp in the token above, instead of being nested below "https://daml.com/ledger-api".

12.8.4.3 Encoding and Signature

Access tokens conforming to the JWT specification are embedded in a larger JSON structure with a separate header and payload.

```
{
  "alg": "RS256",
  "typ": "JWT"
}
{
  "aud": "https://daml.com/jwt/aud/participant/someParticipantId",
  "sub": "someUserId",
  "iss": "someIdpId",
  "exp": 1300819380
}
```

Together they are then base64 encoded, forming the final token's stem. Subsequently, the stem is signed using the cryptographic algorithm identified in the header. The signature itself is also base64-encoded and appended to the stem. The resulting character string takes a shape similar to

```
eyJhbGciOiJSUzI1NiIsInR5cCI6IkpXVCJ9.  
eyJhdWQiOiJodHRwczovL2RhbWwuY29tL2p3dC9hdWQvcGFydGljaXBhbnQvc29tZVBhcnRyY2lwYW50SWQiLCJzd  
DLVPehRLt8WiddI6mwUU1lqIgRbysLK34mgkuzSDQTThCXlEY_S57SHKEQHw-  
Pai0Y0OeGP7wNsT6uq51vBVbRNfxOLwy5owQRm3LEeTbSXMjnnPVrtRrhelVQCsh2AcV4J4bbrAe6YfKGYFBXZOfe  
pN0vWCqmxTbQqnIpSGol85Y0f38nKZeofGT5jcJZaSV7z4Ks15gs9gmlpHorEL6TZLCbX7T064hQeTBFea-  
kxQlUkcfcgmUOMAMa05_4a8fdFz2uHq5km7ylp6pUITogN5MJ-_CVFEwOD0GveOgiUJBBMHDBjq_V_  
DfRE4nZ04tFQ0DDthWpMd0F59JFIhmjZSZT9DWppj6G7VBWpu9aIFPefyX--2U_a00Smt_  
dBBV5A6pvbIgX6ITF2tjEvvOCLHtLKmNTlP8cclna70DCsDIrojnVDMFpLXYLvsP6DhQWkGaRb-  
nz0hLjQE_PtuQzSexrZG5d8tHFS351E2-aUVTKoJuEGHH3n1it-d9yHdt4fAynIbhWUVAervxc-  
oXyrA3-uafrxbIiQCpnw0kQ8K-HwJpkfz_Yqf-luI1FaRiPT9F-cYzwwceNf2_  
2hhmiuGiYp3rVIPwKFauBclvgpPiWSNLc
```

Note that access token generation in the correct format is typically delegated to the identity provider systems. Client application developers are unlikely to need to deal with it directly.

12.9 Explicit Contract Disclosure

In Daml, you must specify up front who can view data using [stakeholder](#) annotations in template definitions. To change who can see the data, you would typically need to recreate a contract with a template that computes different stakeholder parties.

Explicit contract disclosure allows you to delegate contract read rights to non-stakeholders using off-ledger data distribution. This supports efficient, scalable data sharing on the ledger.

Note: Explicit disclosure is activated by default. To deactivate it, configure `participants.participant.ledger-api.enable-explicit-disclosure = false`.

Here are some use cases that illustrate how you might benefit from explicit contract disclosure:

You want to provide proof of the price data for a stock transaction. Instead of subscribing to price updates and potentially being inundated with thousands of price updates every minute, you could serve the price data through a traditional Web 2.0 API. You could then use that API to feed only the current price back into the ledger at the time of use. You get the same validation and security, but reduce the amount of transferred data manyfold.

You want to run an open market on ledger. Rather than making all bids and asks explicitly visible to all marketplace users, you serve market data through standard Web 2.0 APIs. At the point of use, the available bids and asks are fed back into the transactions to get the same activeness and correctness guarantees that would be provided had they been shared through the observer mechanism.

12.9.1 Contract Read Delegation

Contract read delegation allows a party to acquire read rights during command submission over a contract of which it is neither a stakeholder nor an informee.

As an example application where read delegation could be used, consider a simplified trade between two parties. In this example, party **Seller** owns a unit of Digital Asset `Stock` issued by the **StockExchange** party. As the issuer of the stock, **StockExchange** also publishes the stock's `PriceQuotation` as public data, which can be used for settling trades at the correct market value. The **Seller**

announces an offer to sell its stock publicly by creating an `Offer` contract that can be exercised by anyone who can pay the correct market value in terms of `IOU` units.

On the other side, party **Buyer** owns an `IOU` with 10 monetary units, which it wants to use to acquire **Seller's** stock.

The Daml templates used to model the above-mentioned trade are outlined below.

```
module StockExchange where

import Daml.Script
import DA.Assert
import DA.Action

template IOU
  with
    issuer: Party
    owner: Party
    value: Int
  where
    signatory issuer
    observer owner

    choice IOU_Transfer: ()
      with
        target: Party
        amount: Int
        controller owner
      do
        -- Check that the transferred amount is not higher than the current IOU
        value
        assert (value >= amount)
        create this with issuer = issuer, owner = target, value = amount
        -- No need to create a new IOU for owner if the full value is transferred
        if value == amount then pure ()
        else void $ create this with issuer = issuer, owner = owner, value =
        value - amount
        pure ()

template Stock
  with
    issuer: Party
    owner: Party
    stockName: Text
  where
    signatory issuer
    observer owner

    choice Stock_Transfer: ()
      with
        newOwner: Party
        controller owner
      do
        create this with owner = newOwner
        pure ()

-- Expresses the current market value of a stock issued by the issuer.
```

(continues on next page)

(continued from previous page)

```

-- Not modelled in this example: the issuer ensures that only one `PriceQuotation`
-- is active at a time for a specific `stockName`.
template PriceQuotation
  with
    issuer: Party
    stockName: Text
    value: Int
  where
    signatory issuer

    -- Helper choice to allow the controller to fetch this contract without being
    -- a stakeholder.
    -- By fetching this contract, the controller (i.e. `fetcher`) proves
    -- that this contract is active and represents the current market value for
    -- this stock.
    nonconsuming choice PriceQuotation_Fetch: PriceQuotation
      with fetcher: Party
      controller fetcher
      do pure this

template Offer
  with
    seller: Party
    quotationProducer: Party
    offeredAssetCid: ContractId Stock
  where
    signatory seller

    choice Offer_Accept: ()
      with
        priceQuotationCid: ContractId PriceQuotation
        buyer: Party
        buyerIou: ContractId IOU
        controller buyer
        do
          priceQuotation <- exercise
            priceQuotationCid PriceQuotation_Fetch with
              fetcher = buyer
          asset <- fetch offeredAssetCid

          -- Assert the quotation issuer and asset name
          priceQuotation.issuer === quotationProducer
          priceQuotation.stockName === asset.stockName

          _ <- exercise
            offeredAssetCid Stock_Transfer with
              newOwner = buyer

          -- Purchase the stock at the currently published fair price.
          _ <- exercise
            buyerIou IOU_Transfer with target = seller, amount = priceQuotation.
    value
      pure ()

```

The following snippet of [Daml Script](#) models the setup of the trade between the parties.

```

let stockName = "Daml"

stockCid <- submit stockExchange do
  createCmd Stock with
    issuer = stockExchange
    owner = seller
    stockName = stockName

offerCid <- submit seller do
  createCmd Offer with
    seller = seller
    quotationProducer = stockExchange
    offeredAssetCid = stockCid

priceQuotationCid <- submit stockExchange do
  createCmd PriceQuotation with
    issuer = stockExchange
    stockName = stockName
    value = 3

buyerIouCid <- submit bank do
  createCmd IOU with
    issuer = bank
    owner = buyer
    value = 10

```

Settling the trade on-ledger implies that **Buyer** exercises `Offer_Accept` on the `offerCid` contract. But how can **Buyer** exercise a choice on a contract on which it is neither a stakeholder nor a prior informee? The same question applies to **Buyer**'s visibility over the `stockCid` and `priceQuotationCid` contracts.

If **Buyer** plainly exercises the choice as shown in the snippet below, the submission will fail with an error citing missing visibility rights over the involved contracts.

```

-- Command fails with missing visibility over the contracts for buyer
_ <- submit buyer do
  exerciseCmd offerCid Offer_Accept with priceQuotationCid = priceQuotationCid,
  ↪ buyer = buyer, buyerIou = buyerIouCid

```

12.9.1.1 Read delegation using explicit contract disclosure

With the introduction of explicit contract disclosure, **Buyer** can accept the offer from **Seller** without having seen the involved contracts on the ledger. This is possible if the contracts' stakeholders decide to [disclose](#) their contracts to any party desiring to execute such a trade. **Buyer** can attach the disclosed contracts to the command submission that is exercising `Offer_Accept` on **Seller**'s `offerCid`, thus bypassing the visibility restriction over the contracts.

Note: The Ledger API uses the disclosed contracts attached to command submissions for resolving contract and key activeness lookups during command interpretation. This means that usage of a disclosed contract effectively bypasses the visibility restriction of the submitting party over the respective contract. However, the authorization restrictions of the Daml model still apply: the submitted command still needs to be well authorized. The actors need to be properly authorized to

execute the action, as described in [Privacy Through Authorization](#).

12.9.2 How do stakeholders disclose contracts to submitters?

The disclosed contract's details can be fetched by the contract's stakeholder from the contract's associated [CreatedEvent](#), which can be read from the Ledger API via the active contracts and transactions queries (see [Reading from the ledger](#)).

The stakeholder can then share the disclosed contract details to the submitter off-ledger (outside of Daml) by conventional means, such as HTTPS, SFTP, or e-mail. A [DisclosedContract](#) can be constructed from the fields of the same name from the original contract's `CreatedEvent`.

Note: The `created_event_blob` field in `CreatedEvent` (used to construct the [DisclosedContract](#)) is populated **only** on demand for `GetTransactions`, `GetTransactionTrees`, and `GetActiveContracts` streams. To learn more, see [configuring transaction filters](#).

12.9.3 Attaching a disclosed contract to a command submission

A disclosed contract can be attached as part of the `Command`'s [disclosed_contracts](#) and requires the following fields (see [DisclosedContract](#) for content details) to be populated from the original `CreatedEvent` (see above):

template_id - The contract's template id.

contract_id - The contract id.

created_event_blob - The contract's representation as an opaque blob encoding.

Note: Only contracts created starting with Canton 2.8 can be shared as disclosed contracts. In earlier versions, the **CreatedEvent** does not have the required populated `created_event_blob` field and cannot be used as disclosed contracts.

12.9.4 Trading the stock with explicit disclosure

In the example above, **Buyer** does not have visibility over the `stockCid`, `priceQuotationCid` and `offerCid` contracts, so **Buyer** must provide them as disclosed contracts in the command submission exercising `Offer_Accept`. To do so, the contracts' stakeholders must fetch them from the ledger and make them available to the **Buyer**.

Then, the **Buyer** attaches the disclosed contract payloads to the command submission that accepts the offer.

These last two steps are executed using the new Daml Script functions supporting explicit disclosure: `queryDisclosure` and `submitWithDisclosures`.

```
disclosedStock <- fromSome <$> queryDisclosure stockExchange stockCid
disclosedOffer <- fromSome <$> queryDisclosure seller offerCid
disclosedPriceQuotation <- fromSome <$> queryDisclosure stockExchange
  ↪ priceQuotationCid
```

(continues on next page)

(continued from previous page)

```

_ <- submitWithDisclosures buyer [disclosedStock, disclosedOffer,
  ↪disclosedPriceQuotation] do
  exerciseCmd offerCid Offer_Accept with priceQuotationCid = priceQuotationCid,
  ↪buyer = buyer, buyerIou = buyerIouCid

```

Note: For an example using Java bindings for client applications, see the [Java Bindings StockExchange example project](#).

12.9.5 Safeguards

In the example above, what if the **Buyer** is malicious and wants to pay less than the official price quotation for **Seller's** stock? **Buyer** might try to do so by modifying the received `disclosedPriceQuotation` payload received from the **StockExchange** by setting a lower value in the contract's arguments and then using the forged payload as a disclosed contract in the command submission exercising `Offer_Accept` on **Seller's** offer.

12.9.5.1 Contract authentication

Scenarios like the one exemplified above are not possible due to a new technical feature introduced with the explicit contract disclosure feature: Daml contract authentication.

More specifically, each contract's arguments, template-id, signatories, keys, etc. are incorporated into the contract's contract-id as a hash over all the relevant information, ensuring that any tampering leads to a different contract-id than the one submitted. All the honest participants involved in the transaction then catch the misalignment.

In the example above, if the **Buyer's** participant is honest it cannot be tricked and would reject the submission with a `DISCLOSED_CONTRACT_AUTHENTICATION_FAILED`. If **Buyer's** participant is also malicious and submits a confirmation request with the malformed payload, the other participants involved in the transaction detect the misalignment and reject the request.

12.9.5.2 Business logic safeguards

As good practice, each Daml application workflow should have business logic preconditions that safeguard against misuse.

In our example, the `Offer_Accept` choice has a *flexible* controller (`buyer`) that is provided as an argument. Since any party can exercise the choice by providing the `disclosedOffer` disclosed contract at command submission time, the choice body should contain safeguards that disallow malicious use, modeled in our example as Daml asserts.

```

-- Assert the quotation issuer and asset name
priceQuotation.issuer === quotationProducer
priceQuotation.stockName === asset.stockName

```

When modeling Daml workflows using disclosed contracts, such safeguards assure:

- a disclosed contract's user that its contents are validated against expected conditions.

a disclosed contract's owner that it is used within the expected agreement.

In our case, the Daml assertions in `Offer_Accept` ensure that the price quotation is coming from a party that the **Seller** is trusting (**Issuer**) and that it actually matches stock that the **Seller** intends to sell.

Chapter 13

Resource Management in Daml Application Design

This section discusses approaches to avoiding potential resource pitfalls by strengthening Daml contract design.

Note: In this document, we focus on building resilience into the system by writing performant Daml code at design time. We are not concerned with ledger optimization. Read more about [Canton performance and scaling](#).

13.1 Managing Latency and Throughput

13.1.1 Problem Definition

Latency is a measure of how long a business transaction takes to complete. Throughput measures, on average, the number of business transactions possible per second while taking into account any lower or upper bounds which may point to bottlenecks. Defense against latency and throughput issues can be written into the Daml application during design.

First we need to identify the potential bottlenecks in a Daml application. We can do this by analyzing the sync-domain-specific transactions.

Each Daml business transaction kicks off when a Ledger API client sends the commands `create` or `exercise` to a participant.

Important:

Ledger transactions are not synonymous with business transactions.

Often a complete business transaction spans multiple workflow steps and thus multiple ledger transactions.

Multiple business transactions can be processed in a single ledger transaction through batching.

Expected ledger transaction latencies are on the order of 0.5-1 seconds on database sequencers, and multiple seconds on blockchain sequencers.

Refer to the [Daml execution model](#) that describes a ledger transaction processed by the Canton ledger. The table below highlights potential resource-intensive activities at each step.

Step	Participant	Resources used	Possible bottleneck drivers
Inter-pretation	Submitting participant node	<ol style="list-style-type: none"> 1. CPU 2. Memory 3. DB read access 	<ol style="list-style-type: none"> 1. Calculation complexity 2. Size and number of variables 3. Number of contract fetches
Blinding	Submitting participant node	CPU/memory	Number and size of views
Submission	Submitting participant node Sequencer	<ol style="list-style-type: none"> 1. CPU 2. Memory 	<ol style="list-style-type: none"> 1. Serialization/deserialization 2. Transaction size/number of views
Sequencing	Sequencer	<ol style="list-style-type: none"> 1. Backend storage 2. Network bandwidth 	<ol style="list-style-type: none"> 1. Transaction size 2. Transaction size/number of views
Validation	Receiving participant nodes	<ol style="list-style-type: none"> 1. Network bandwidth 2. CPU 3. Memory 4. DB read throughput 	<ol style="list-style-type: none"> 1. Transaction size -> download, deserialization, storage costs 2. Computation complexity 3. Number of contract fetch reads 4. Number and size of variables
Confirmation	Validating participant nodes Sequencer	<ol style="list-style-type: none"> 1. Network bandwidth 2. Sequencer network 3. Backend write throughput 	Number of confirming parties
Mediation	Mediator nodes	<ol style="list-style-type: none"> 1. Network throughput 2. CPU 3. Memory 	Number of confirming parties
Commit	Mediator nodes Sequencer	<ol style="list-style-type: none"> 1. CPU 2. Memory 3. DB 4. Network bandwidth 	Number of confirming parties

13.1.1.1 Possible Throughput Bottlenecks in Order of Likelihood

1. Transaction size causing high serialization/deserialization and encryption/decryption costs on participant nodes.
2. Transaction size causing sequencer backend overload, especially on blockchains.
3. High interpretation and validation cost due to calculation complexity or memory use.
4. Large number of involved nodes and associated network bandwidth on sequencer.

Latency can also be affected by the above factors. However, baseline latency usually has more to do with system set-up issues (DB or blockchain latency) rather than Daml modeling problems.

13.1.1.2 Solutions

1. Minimize transaction size.

Each of the following actions in Daml adds a node to the transaction containing the payload of the contract being acted on. A large number of such operations, and/or operations of this kind on large contracts, are the most common cause of performance bottlenecks.

```
create
fetch
fetchByKey
lookupByKey
exercise
exerciseByKey
archive
```

Use the above actions sparingly. For example, if contracts have intermediary states within a transaction, you can often skip them by writing only the end state. For example:

```
template Incrementor
with
p : Party
n : Int
where
signatory p

choice Increment : ContractId Incrementor
  controller p
  do create this with n = n+1

-- This adds all m-1 intermediary versions of
-- the contract to the transaction tree
choice BadIncrementMany : ContractId Incrementor
  with m : Int
  controller p
  do foldlA (\self' _ -> exercise self' Increment) self [1..m]

-- This only adds the end result to the transaction
choice GoodIncrementMany : ContractId Incrementor
  with m : Int
  controller p
  do create this with n = n+m
```

When you need to read a contract, or act on a single contract in multiple ways, you can often bundle those operations into a single action. For example:

```

template Asset
with
  issuer : Party
  owner  : Party
  quantity : Decimal
where
  signatory [issuer, owner]

  -- BadMerge acts on each of the otherCids three times:
  -- Once for validation
  -- Once to extract the quantities
  -- Once to archive
  choice BadMerge : ContractId Asset
    with otherCids : [ContractId Asset]
    controller owner
    do
      -- validate the cids.
      forA_ otherCids (\cid -> do
        other <- fetch cid
        assert (other.issuer == issuer && other.owner == owner))

      -- extract the quantities
      quantities <- forA otherCids (\cid -> do
        other <- fetch cid
        return other.quantity)

      -- archive the others
      forA_ otherCids archive

      create this with quantity = quantity + sum quantities

  -- Allow us to do a fetch and an archive in one action
  choice ConsumingFetch : Asset
    controller owner
    do return this

  -- GoodMerge only acts on each of the other assets once.
  choice GoodMerge : ContractId Asset
    with otherCids : [ContractId Asset]
    controller owner
    do
      -- Get and archive the others
      others <- forA otherCids (`exercise` ConsumingFetch)

      -- validate
      forA_ others (\other -> do
        assert (other.issuer == issuer && other.owner == owner))

      -- extract the quantities
      let quantities = map (.quantity) others

      create this with quantity = quantity + sum quantities

```

Separate templates for large payloads that change rarely and require minimum access from those for fields that change with almost every action. This optimizes resource consumption for multiple business transactions.

This batching approach makes updates in one transaction submission rather than requiring separate transactions for each update. Note: this option can cause a small increase in latency and may increase the possibility of command failure but this can be avoided. For example:

```
template T
with
p : Party
where
signatory p

choice Foo : ()
  controller p
  do return ()

batching : Script ()
batching = do
p <- allocateParty "p"

-- without batching we have 10 ledger
-- transactions.
cid1 <- submit p do createCmd T with ..
cid2 <- submit p do createCmd T with ..
cid3 <- submit p do createCmd T with ..
cid4 <- submit p do createCmd T with ..
cid5 <- submit p do createCmd T with ..

submit p do exerciseCmd cid1 Foo
submit p do exerciseCmd cid2 Foo
submit p do exerciseCmd cid3 Foo
submit p do exerciseCmd cid4 Foo
submit p do exerciseCmd cid5 Foo

-- With batching, there are only two ledger transactions.
cids <- submit p do
replicateA 5 $ createCmd T with ..
submit p do
forA_ cids (`exerciseCmd` Foo)
```

2. CPU and memory issues: Use the [Daml profiler](#) to analyze Daml code execution.
3. Once you feel interpretation is not the bottleneck, scale up your machine.

Tip: Profile the JVM and monitor your databases to see where the bottlenecks occur.

13.2 Avoid Contention Issues

Measuring the performance of business applications involves more than considering the transactions per second and transaction latency of the underlying blockchain and Distributed Ledger Technology (DLT). Blockchains are distributed systems; even the highest-performance blockchains have considerably higher transaction latencies than traditional databases. These factors make the systems prone to contention, which can stifle the performance of applications when not handled appropriately.

It is, unfortunately, easy to design low-performance applications even on a high-performance

blockchain system. Applications that initially perform well may fail under pressure. It is better to plan around contention in your application design than to fix issues later. The marginal cost of including extra business logic within a blockchain transaction is often small.

Contention is expected in distributed systems. The aim is to reduce it to acceptable levels and handle it gracefully, not to eliminate it at all costs. If contention only occurs rarely, it may be cheaper for both performance and complexity to simply let the occasional allocation fail and retry, rather than implement an advanced technique to avoid it.

As an added benefit to reducing contention issues, carefully bundling or batching strategic business logic can improve performance by yielding business transaction throughput that far exceeds the blockchain transaction throughput.

13.2.1 Contention in Daml

Daml uses an unspent transaction output (UTXO) ledger model. UTXO models enable higher performance by supporting parallel transactions. This means that you can send new transactions while other transactions are still processing. The downside is that contention can occur if a second transaction arrives while a conflicting earlier transaction is still pending.

Daml guarantees that there can only be one consuming choice exercised per contract. If you try to commit two transactions that would consume the same contract, you have write-write contention.

Contention can also result from incomplete or stale knowledge. For example, a contract may have been archived, but a client hasn't yet been notified due to latencies or a privacy model might prevent the client from ever knowing. If you try to commit two transactions on the same contract where one transaction reads and the other one consumes an input, you run the risk of a read-write contention.

A contract is considered pending when you do not know if the output has been consumed. It is best to assume that your transactions will go through and to treat pending ones as probably consumed. You must also assume that acting on a pending contract will fail.

You need to wait while the sequencer is processing a transaction in order to confirm that an input was consumed from a consuming input request. If you do not get confirmation back from the first transaction before submitting a second transaction on the same contract, the sequence is not guaranteed. The only way to avoid this conflict is to control the sequence of those two transactions.

Ledger state is read in the following places within the [Daml Execution Model](#):

1. A client submits a command based on the client's latest view of the state of the shared ledger. The command might include references to `ContractIds` that the client believes are active.
2. During interpretation, ledger state is used to look up active contracts.
3. During validation, ledger state is again used to look up contracts and to validate the transaction by reinterpreting it.

Contention can occur both between #1 and #2 and between #2 and #3:

The client is constructing the command in #1 based on contracts it believes to be active. But by the time the participant performs interpretation in #2, it has processed the commit of another transaction that consumed those contracts. The participant node rejects the command due to contention.

The participant successfully constructs a transaction in #2 based on contracts it believes to be active. But by the time validation happens in #3, another transaction that consumes the same contracts has already been sequenced. The validating participants reject the command due to contention.

The complete and relevant ledger state at the time of the transaction is known only after sequencing, which happens between #2 and #3. That ledger state takes precedence to ensure double spend protection.

Contention slows performance significantly. While you cannot avoid contention completely, you can design logic to minimize it. The same considerations apply to any UTXO ledger.

13.2.2 Reduce Contention

Contention is natural and expected when programming within a distributed system like Daml in which every action is asynchronous. It is important to understand the different causes of contention, be able to diagnose the root cause if errors of this type occur, and be able to avoid contention by designing contracts appropriately.

You can use different techniques to manage contention and to improve performance by increasing throughput and decreasing latency. These techniques include the following:

- Add retry logic.

- Run transactions that have causality in series.

- Bundle or batch business logic to increase business transaction throughput.

- Maximize parallelism with techniques such as sharding, while ensuring no contention between shards.

- Split contracts across natural lines to reduce single, high-contention contracts.

- Avoid write-write and write-read contention on contracts. This type of contention occurs when one requester submits a transaction with a consuming exercise on a contract while another requester submits another exercise or a fetch on the same contract. This type of contention cannot be eliminated entirely, since there will always be some latency between a client submitting a command to a participant and other clients learning of the committed transaction. Here are a few scenarios and specific measures you can take to reduce this type of collision:

- Shard data. Imagine you want to store a user directory on the ledger. At the core, this is of type `[(Text, Party)]`, where `Text` is a display name and `Party` is the associated `Party`. If you store this entire list on a single contract, any two users wanting to update their display name at the same time will cause a collision. If you instead keep each `(Text, Party)` on a separate contract, these write operations become independent from each other.

A helpful analogy when structuring your data is to envision that a template defines a table, where a contract is a row in that table. Keeping large pieces of data on a contract is like storing big blobs in a database row. If these blobs can change through different actions, you have write conflicts.

- Use non-consuming choices, where possible, as they do not collide. Non-consuming choices can be used to model events that have occurred, so instead of creating a short-lived contract to hold some data that needs to be referenced, that data could be recorded as a ledger event using a non-consuming choice.
- Avoid workflows that encourage multiple parties to simultaneously exercise a consuming choice on the same contract. For example, imagine an auction contract containing a field `highestBid : (Party, Decimal)`. If Alice tries to bid \$100 at the same time that Bob tries to bid \$90, it does not matter that Alice's bid is higher. The sequencer rejects the second because it has a write collision with the first transaction. It is better to record the bids in separate `Bid` contracts, which can be updated independently. Think about how you would structure this data in a relational database to avoid data loss due to race conditions.
- Think carefully about storing `ContractIds`. Imagine that you create a sharded user directory according to the first bullet in this list. Each user has a `User` contract that stores

their display name and party. Now assume that you write a chat application, where each `Message` contract refers to the sender by `ContractId User`.

If a user changes the display name, that reference goes stale. You either have to modify all messages that the user ever sent, or you cannot use the sender contract in Daml.

Contract keys can be used to make this link inside Daml. If the only place you need to link `Party` to `User` is in the user interface, it might be best to not store contract references in Daml at all.

13.2.3 Example Application with Techniques for Reducing Contention

The example application below illustrates the relationship between blockchain and business application performance, as well as the impact of design choices. Trading, settlement, and related systems are core use cases of blockchain technology, so this example demonstrates different ways of designing such a system within a UTXO ledger model and how the design choices affect application performance.

13.2.3.1 The Example Minimal Settlement System

This section defines the requirements that the example application should fulfill, as well as how to measure its performance and where contention might occur. Assume that there are initial processes already in place to issue assets to parties. All of the concrete numbers in the example are realistic order-of-magnitude figures that are for illustrative purposes only.

Basic functional requirements for the example application

A trading system is a system that allows parties to swap assets. In this example, the parties are Alice and Bob, and the assets are shares and dollars. The basic settlement workflow could be:

1. **Proposal:** Alice offers Bob to swap one share for \$1.
2. **Acceptance:** Bob agrees to the swap.
3. **Settlement:** The swap is settled atomically, meaning that at the same time Alice transfers \$1 to Bob, Bob transfers one share to Alice.

Practical and security requirements for the example application

The following list adds some practical matters to complete the rough functional requirements of an example minimal trading system.

Parties can hold *asset positions* of different asset types which they control.

- An asset position consists of the type, owner, and quantity of the asset.
- An asset type is usually the combination of an on-ledger issuer and a symbol (such as currency, CUSIP, or ISIN).

Parties can transfer an asset position (or part of a position) to another party.

Parties can agree on a settlement consisting of a swap of one position for another.

Settlement happens atomically.

There are no double spends.

It is possible to constrain the *total asset position* of an owner to be non-negative. In other words, it is possible to ensure that settlements are funded. The total asset position is the sum of the quantities of all assets of a given type by that owner.

Performance measurement in the example application

Performance in the example can be measured by latency and throughput; specifically, settlement latency and settlement throughput. Another important factor in measuring performance is the ledger transaction latency.

Settlement latency: the time it takes from one party wanting to settle (just before the proposal step) to the time that party receives final confirmation that the settlement was committed (after the settlement step). For this example, assume that the best possible path occurs and that parties take zero time to make decisions.

Settlement throughput: the maximum number of settlements per second that the system as a whole can process over a long period.

Transaction latency: the time it takes from when a client application submits a command or transaction to the ledger to the time it receives the commit confirmation. The length of time depends on the command. A transaction settling a batch of 100 settlements will take longer than a transaction settling a single swap. For this example, assume that transaction latency has a simple formula of a fixed cost `fixed_tx` and a variable processing cost of `var_tx` times the number of settlements, as shown here:

```
transaction latency = fixed_tx + (var_tx * #settlements)
```

Note that the example application does not assign any latency cost to settlement proposals and acceptances.

For the example application, assume that:

- `fixed_tx` = 250ms
- `var_tx` = 10ms

To set a baseline performance measure for the example application, consider the simplest possible settlement workflow, consisting of one proposal transaction plus one settlement transaction done back-to-back. The following formula approximates the settlement latency of the simple workflow:

```
(2 * fixed_tx) + var_tx  
= (2 * 250ms) + 10ms  
= 510ms
```

To find out how many settlements per second are possible if you perform them in series, throughput evaluates to the following formula (there are 1,000ms in one second):

```
1000ms / (fixed_tx + var_tx) settlements per second  
= 1000ms / (250ms + 10ms)  
= 1000 / 260  
= 3.85 or ≈ 4 settlements per second
```

These calculations set the optimal baselines for a high performance system.

The next goal is to increase throughput without dramatically increasing latency. Assume that the underlying DLT has limits on total throughput and on transaction size. Use a simple cost model in a unit called `dlt_min_tx` representing the minimum throughput unit in the DLT system. An empty transaction has a fixed cost `dlt_fixed_tx` which is:

```
dlt_fixed_tx = 1 dlt_min_tx
```

Assume that the ratio of the marginal throughput cost of a settlement to the throughput cost of a transaction is roughly the same as the ratio of marginal latency to transaction latency (shown

previously). A marginal settlement throughput cost `dlt_var_tx` can then be determined by this calculation:

```
dlt_var_tx = ratio * dlt_fixed_tx
= dlt_var_tx = (var_tx / fixed_tx) * dlt_fixed_tx
= dlt_var_tx = 10sm/250ms * dlt_fixed_tx
= dlt_var_tx = 0.04 * dlt_fixed_tx
```

and, since from previously

```
dlt_fixed_tx = 1 dlt_min_tx
```

then

```
dlt_var_tx = 0.04 * dlt_min_tx
```

Even with good parallelism, ledgers have limitations. The limitations might involve CPUs, databases, or networks. Calculate and design for whatever ceiling you hit first. Specifically, there is a maximum throughput `max_throughput` (measured in `dlt_min_tx/second`) and a maximum transaction size `max_transaction` (measured in `dlt_min_tx`). For this example, assume that `max_throughput` is limited by being CPU-bound. Assume that there are 10 CPUs available and that an empty transaction takes 10ms of CPU time. For each second:

```
max_throughput = 10 * each CPU's capacity
```

Each `dlt_min_tx` takes 10ms and there are 1,000 ms in a second. The capacity for each CPU is then 100 `dlt_min_tx` per second. The throughput calculation becomes:

```
max_throughput = 10 * 100 dlt_min_tx/second
= max_throughput = 1,000 dlt_min_tx/second
```

Similarly, `max_transaction` could be limited by message size limit. For this example, assume that the message size limit is 3 MB and that an empty transaction `dlt_min_tx` is 1 MB. So

```
max_transaction = 3 * dlt_min_tx
```

One of the three transactions needs to hold an approval with no settlements. That leaves the equivalent of $(2 * dlt_min_tx)$ available to hold many settlements in the biggest possible transaction. Using the ratio described earlier, each marginal settlement `dlt_var_tx` takes $0.04 * dlt_min_tx$. So the maximum number of settlements per second is:

```
(2 * dlt_min_tx) / (0.04 * dlt_min_tx)
= 50 settlements/second
```

Using the same assumptions, if you process settlements in parallel rather than in series (with only one settlement per transaction), latency stays constant while settlement throughput increases. Earlier, it was noted that a simple workflow can be $(2 * fixed_tx) + var_tx$. In the DLT system, the simple workflow calculation is:

```
(2 * dlt_min_tx) + dlt_var_tx
= (2 * dlt_min_tx) + (0.04 * dlt_min_tx)
= 2.04 * dlt_min_tx
```

It was assumed earlier that `max_throughput` is 1,000 `dlt_min_tx/second`. So the maximum number of settlements per second possible through parallel processing alone in the example DLT system is:

$1,000/2.04$ settlements per second

$= 490.196$ or ~ 490 settlements per second

These calculations provide a baseline when comparing various techniques that can improve performance. The techniques are described in the following sections.

13.2.3.2 Prepare Transactions for Contention-Free Parallelism

This section examines which aspects of UTXO ledger models can be processed in parallel to improve performance. In UTXO ledger models, the state of the system consists of a set of immutable contracts, sometimes also called UTXOs.

Only two things can happen to a contract: it is created and later it is consumed (or spent). Each transaction is a set of input contracts and a set of output contracts, which may overlap. The transaction creates any output contracts that are not also consumed in the same transaction. It also consumes any input contracts, unless they are defined as non-consumed in the smart contract logic.

Other than smart contract logic, the execution model is the same for all UTXO ledger systems:

1. **Interpretation:** the submitting party precalculates the transaction, which consists of input and output contracts.
2. **Submission:** the submitting party submits the transaction to the network.
3. **Sequencing:** the consensus algorithm for the network assigns the transaction a place in the total order of all transactions.
4. **Validation:** the transaction is validated and considered valid if none of the inputs were already spent by a previous transaction.
5. **Commitment:** the transaction is committed.
6. **Response:** the submitting party receives a response that the transaction was committed.

The only step in this process which has a sequential component is sequencing. All other stages of transaction processing are parallelizable, which makes UTXO a good model for high-performance systems. However, the submitting party has a challenge. The interpretation step relies on knowing possible input contracts, which are by definition unspent outputs from a previous transaction. Those outputs only become known in the response step, after a minimum delay of `fixed_tx`.

For example, if a party has a single \$1,000 contract and wants to perform 1,000 settlements of \$1 each, sequencing in parallel for all 1,000 settlements leads to 1,000 transactions, each trying to consume the same contract. Only one succeeds, and all the others fail due to contention. The system could retry the remaining 999 settlements, then the remaining 998, and so on, but this does not lead to a performant system. On the other hand, using the example latency of 260ms per settlement, processing these in series would take 260s or four minutes 20s, instead of the theoretical optimum of one second given by `max_throughput`. The trading party needs a better strategy. Assume that:

$\text{max_transaction} > \text{dlt_fixed_tx} + 1,000 * \text{dlt_var_tx} = 41 \text{ dlt_min_tx}$

The trading party could perform all 1,000 settlements in a single transaction that takes:

$\text{fixed_tx} + 1,000 * \text{var_tx} = 10.25\text{s}$

If the latency limit is too small or this latency is unacceptable, the trading party could perform three steps to split \$1,000 into:

$10 * \$100$

$100 * \$10$

$1,000 * \$1$

and perform the 1,000 settlements in parallel. Latency would then be theoretically around:

$$3 * \text{fixed_tx} + (\text{fixed_tx} + \text{var_tx}) = 1.01\text{s}$$

However, since the actual settlement starts after 750 ms, and the `max_throughput` is 1,000 `dlt_min_tx/s`, it would actually be:

$$0.75\text{s} + (1,000 * (\text{dlt_fixed_tx} + \text{dlt_var_tx})) / 1,000 \text{ dlt_min_tx/s} \\ = 1.79\text{s}$$

These strategies apply to one particular situation with a very static starting state. In a real-world high performance system, your strategy needs to perform with these assumptions:

There are constant incoming settlement requests, which you have limited ability to predict. Treat this as an infinite stream of random settlements from some distribution and maximize settlement throughput with reasonable latency.

Not all settlements are successful, due to withdrawals, rejections, and business errors.

To compare between different techniques, assume that the settlement workflow consists of the steps previously illustrated with Alice and Bob:

1. **Proposal:** proposal of the settlement
2. **Acceptance:** acceptance of the settlement
3. **Settlement:** actual settlement

These steps are usually split across two transactions by bundling the acceptance and settlement steps into one transaction. Assume that the first two steps, proposal and acceptance, are contention-free and that all contention is on settlement in the last step. Note that the cost model allocates the entire latency and throughput costs `var_tx` and `dlt_var_tx` to the settlement, so rather than discussing performant trading systems, the concern is for performant settlement systems. The following sections describe some strategies for trading under these assumptions and their tradeoffs.

13.2.3.3 Non-UTXO Alternative Ledger Models

As an alternative to a UTXO ledger model, you could use a replicated state machine ledger model, where the calculation of the transaction only happens after the sequencing.

The steps would be:

1. **Submission:** the submitting party submits a command to the network.
2. **Sequencing:** the consensus algorithm of the network assigns the command a place in the total order of all commands.
3. **Validation:** the command is evaluated to a transaction and then validated.
4. **Response:** the submitting party receives a response about the effect of the command.

Pros

This technique has a major advantage for the submitting party: no contention. The party pipes the stream of incoming transactions into a stream of commands to the ledger, and the ledger takes care of the rest.

Cons

The disadvantage of this approach is that the submitting party cannot predict the effect of the command. This makes systems vulnerable to attacks such as frontrunning and reordering.

In addition, the validation step is difficult to optimize. Command evaluation may still depend on the effects of previous commands, so it is usually done in a single-threaded manner. Transaction evaluation is at least as expensive as transaction validation. Simplifying and assuming that `var_tx` is mostly due to evaluation and validation cost, a single-threaded system would be limited to $1s / \text{var_tx} = 100$ settlements per second. It could not be scaled further by adding more hardware.

13.2.3.4 Simple Strategies for UTXO Ledger Models

To attain high throughput and scalability, UTXO is the best option for a ledger model. However, you need strategies to reduce contention so that you can parallelize settlement processing.

Batch transactions sequentially

Since $(\text{var_tx} \ll \text{fixed_tx})$, processing two settlements in one transaction is much cheaper than processing them in two transactions. One strategy is to batch transactions and submit one batch at a time in series.

Pros

This technique completely removes contention, just as the replicated state machine model does. It is not susceptible to reordering or frontrunning attacks.

Cons

As in the replicated state machine technique, each batch is run in a single-threaded manner. However, on top of the evaluation time, there is transaction latency. Assuming a batch size of $N < \text{max_settlements}$, the latency is:

$$\text{fixed_tx} + N * \text{var_tx}$$

and transaction throughput is:

$$N / (\text{fixed_tx} + N * \text{var_tx})$$

As N goes up, this tends toward $1 / \text{var_tx} = 100$, which is the same as the throughput of replicated state machine ledgers.

In addition, there is the `max_settlements` ceiling. Assuming `max_settlements = 50`, you are limited to a throughput of $50 / 0.75 = 67$ settlement transactions per second, with a latency of 750ms. Assuming that the proposal and acceptance steps add another transaction before settlement, the settlement throughput is 67 settlements per second, with a settlement latency of one second. This is better than the original four settlements per second, but far from the 490 settlements per second that is achievable with full parallelism.

Additionally, the success or failure of a whole batch of transactions is tied together. If one transaction fails in any way, all will fail, and the error handling is complex. This can be somewhat mitigated by using features such as Daml exception handling, but contention errors cannot be handled. As long as there is more than one party acting on the system and contention is possible between parties (which is usually the case), batches may fail. The larger the batch is, the more likely it is to fail, and the more costly the failure is.

Use sequential processing or batching per asset type and owner

In this technique, assume that all contention is within the asset allocation steps. Imagine that there is a single contract on the ledger that takes care of all bookkeeping, as shown in this Daml code snippet:

```
template AllAssets
  with
    -- A map from owner and type to quantity
    holdings : Map Party (Map AssetType Decimal)
  where
    signatory (keys holdings)
```

This is a typical pattern in replicated state machine ledgers, where contention does not matter. On a UTXO ledger, however, this pattern means that any two operations on assets experience contention. With this representation of assets, you cannot do better than sequential batching. There are many additional issues with this approach, including privacy and contract size.

Since you typically only need to touch one owner's asset of one type at a time and constraints such as non-negativity are also at that level, assets are usually represented by asset positions in UTXO ledgers, as shown in this Daml code snippet:

```
template
  with
    assetType : AssetType
    owner : Party
    quantity : Decimal
  where
    signatory assetType.issuer, owner
```

An asset position is a contract containing a triple (owner, asset type, and quantity). The total asset position of an asset type for an owner is the sum of the quantities for all asset positions with that owner and asset type. If the settlement transaction touches two total asset positions for the buy-side and two total asset positions for the sell-side, batching by asset type and owner does not help much.

Imagine that Alice wants to settle USD for EUR with Bob, Bob wants to settle EUR for GBP with Carol, and Carol wants to settle GBP for USD with Alice. The three settlement transactions all experience contention, so you cannot do better than sequential batching.

However, if you could ensure that each transaction only touches one total asset position, you could then apply sequential processing or batching per total asset position. This is always possible to do by decomposing the settlement step into the following:

1. **Buy-side allocation:** the buy-side splits out an asset position from their total asset position and allocates it to the settlement.
2. **Sell-side allocation:** the sell-side splits out an asset position from their total asset position and allocates it to the settlement.
3. **Settlement:** the asset positions change ownership.
4. **Buy-side merge:** the buy-side merges their new position back into the total asset position.
5. **Sell-side merge:** the sell-side merges their new position back into the total asset position.

This does not need to result in five transactions.

Buy-side allocation is usually done as part of a settlement proposal.

Sell-side allocation is typically handled as part of the settlement.

Buy-side merge and sell-side merge technically do not need any action. By definition of total asset positions, merging is an optional step. It is easy to keep things organized without extra transactions. Every time a total asset position is touched as part of buy-side allocation or sell-side allocation above, you merge all positions into a single one. As long as there is a similar amount of inbound and outbound traffic on the total asset position, the number of individual positions stays low.

Pros

Assuming that a settlement is considered complete after the settlement step and that you bundle the allocation steps above into the proposal and settlement steps, the system performance will stay at the optimum settlement latency of 510ms.

Also, if there are enough open settlements on distinct total asset positions, the total throughput may reach up to the optimal 490 settlements per second.

With batch sizes of $N=50$ for both proposals and settlements and sufficient total asset positions with open settlements, the maximum theoretical settlement throughput is:

$$\frac{50 \text{ stls} * 1,000 \text{ dlt_min_tx/s}}{500 \text{ stls/s}} / (2 * \text{dlt_fixed_tx} + 50 * \text{dlt_var_tx}) = 12,$$

Cons

Without batching, you are limited to the original four outgoing settlements per second, per total asset position. If there are high-traffic assets, such as the USD position of a central counterparty, this can bottleneck the system as a whole.

Using higher batch sizes, you have the same tradeoffs as for sequential batching, except that it is at a total asset position level rather than a global level. Latency also scales exactly as it does for sequential batching.

Using a batch size of 50, you would get settlement latencies of around 1.5s and a maximum throughput per total asset position of 67 settlements per second, per total asset position.

Another disadvantage is that allocating the buy-side asset in a transaction before the settlement means that asset positions can be locked up for short periods.

Additionally, if the settlement fails, the already allocated asset needs to be merged back into the total asset position.

13.2.3.5 Shard Asset Positions for UTXO Ledger Models

In systems where peak loads on a single total asset position is in the tens or hundreds of settlements per second, more sophisticated strategies are needed. The total asset positions in question cannot be made up of a single asset position. They need to be sharded.

Shard total asset positions without global constraints

Consider a total asset position that represents a bookkeeping position without any on-ledger constraints. For example, the trading system may deal with fiat settlement off-ledger, and you simply want to record a balance, whether it is positive or negative. In this situation, you can easily get rid of contention altogether by assigning all allocations an arbitrary amount. To allocate \$1 to a settlement, write two new asset positions of \$1 and -\$1 to the ledger, then use the \$1 to allocate. The total asset position is unchanged.

Pros

This approach removes all contention on a total asset position.

Trading between two such total asset positions without global constraints can run at the theoretically optimal latency and throughput. Combining this with batching of batch size 50, it is possible to achieve settlements per second up to the same 12,500 settlements per second per total asset position that are possible globally.

Cons

Besides the inability to enforce any global constraints on the total asset position, this creates many new contracts. At 500 settlements per second, two allocations per settlement, and two new assets per allocation, that results in 2,000 new asset positions per second, which adds up quickly.

This effect has to be mitigated by a netting automation that nets them up into a single position once a period (for example, every time it sees ≥ 100 asset positions for a total position). This automation does not contend with the trading, but it adds up to 20 large transactions per second to the system and slightly reduces total throughput.

Shard total asset positions with global constraints

As an example of a global constraint, assume that the total asset position has to stay positive. This is usually done by ensuring that each individual asset position is positive. If that is the case, the strategy is to define a sharding scheme where the total position is decomposed into N smaller shard positions and then run sequential processing or batching per shard position.

Each asset position has to be clearly assignable to a single shard position so that there is no contention between shards. The partitioning of the total asset position does not have to be done on-ledger. If the automation for all shards can communicate off-ledger, it is possible to run a sharding strategy where you simply set the total number of desired asset positions.

For example, assume that there should be 100 asset positions for a total asset position with some minimal value.

The automation keeps track of a synchronized pending set of asset positions, which marks asset positions that are in use.

Every time the automation triggers (which may happen concurrently), it looks at how many asset positions there are relative to the desired 100 and how much quantity is needed to allocate the open settlements.

It then selects an appropriate set of non-pending asset positions so that it can allocate the open settlements and return new asset positions to move the total number closer to 100.

Before sending the transaction, it adds those positions to the pending set to make sure that another thread does not also use them.

Alternatively, if you have a sufficiently large total position compared to settlement values, you can pick the 99th percentile p_{99} of settlement values and maintain $N-1$ positions of value between p_{99} and $2 * p_{99}$ and one of the (still large) remainder. 99% of transactions will be processed in the $N-1$ shard positions, and the remaining 1% will be processed against the remaining pool. Whenever a shard moves out of the desired range, it is balanced against the pool.

Pros

Assuming that there is always enough liquidity in the total asset position, the performance can be the same as without global constraints: up to 12,500 settlements per second on a single total asset position.

Cons

If settlement values are large compared to total asset holdings, this technique helps little. In an extreme case, if every settlement needs more than 50% of the total holding, it does not perform any better than the sequential processing or batching per asset type and owner technique.

In realistic scenarios where settlement values are distributed on a broad range relative to total asset position and those relativities change as holdings go up and down, developing strategies that perform optimally is complex. There are competing priorities that need to be balanced carefully:

- Keeping the total number of asset positions limited so that the number of active contracts does not impact system performance.

- Having sufficient large asset positions so that frequent small settlements can be processed in parallel.

- Having a mechanism that ensures large settlements, possibly requiring as much as 100% of the available total asset position, are not blocked.

13.3 Managing Active Contract Set (ACS) Size

13.3.1 Problem Definition

The Active Contract Set (ACS) size makes up the load related to the number of active contracts in the system at any one time. It means the totality of all the contracts that have been created but not yet archived. ACS size may come from a deliberate Daml workflow design, but the size may also be unexpected when insufficient care is given to supporting and auxiliary contract lifetimes.

Tip: See the documentation on [Daml contracts](#) for more information.

In Daml systems, ACS size can reach orders of magnitude higher than synonymous loads in common database or blockchain systems. When the ACS size is in the high 100s GBs or TBs, local database access performance may deteriorate. We will look at potential issues around large ACS size and possible solutions.

13.3.2 Relational Databases

Large ACS can have a negative impact on many aspects of system performance in relational databases. The following points focus on PostgreSQL as the underlying database; the details differ in the case of Oracle but the results are similar.

Large ACS size directly affects the resource consumption and performance of a Ledger API client application dealing with a large data set that may not fit into the memory or the application database.

ACS size directly affects the speed at which the ACS can be transmitted from the Ledger API server using the `ActiveContractService`. In extreme cases, it could take hours to transfer the complete set requested by the application due to the limits imposed by the gRPC channel capacity and the speed of storage queries.

Increased latency is a less direct impact which shows up wherever a query is issued to the database index to make progress. Large ACS size means that the corresponding indices are also large, and at a certain point they will no longer fit into the shared-buffer space. It then takes increasingly longer for the database engine to produce query results. This affects activities such as contract lookups during the command submission, transaction tree streaming, or pointwise transaction lookups.

Large ACS size may affect the speed at which the database underpinning the participant ingests new transactions. Normally, as new updates pour in the write-ahead log commits the table and index changes immediately. Those updates come in two shapes; full-page writes or differential writes. With large volumes, many are full-page writes.

Finally, many dirty pages also translate into prolonged and expensive flushes to the disk as part of the checkpointing process.

13.3.2.1 Solutions

Pay attention to the lifetime of the contracts. Make sure that the supporting and auxiliary contracts don't clutter the ACS and archive them as soon as it is practical to do so.

Set up a frequent pruning schedule. Be aware that pruning is only effective if there are archived contracts available for pruning. If all contracts are still active, pruning has limited success. Refer to our [pruning documentation](#) for more information.

Implement an ODS in your ledger client application to limit reliance on read access to the ACS. Do this whenever you notice that the time to initialize the application from the ACS exceeds your pain level.

Monitor database performance.

- Monitor the disk read and write activity. Look for sudden changes in the operation patterns. For instance, a sudden increase in the disk's read activity may be a sign of indices no longer fitting into the shared buffers.
- Observe the performance of the database queries. Check our monitoring documentation for [query metrics](#) that can assist. You may also consider setting up a [log_min_duration_statement parameter](#) in the PostgreSQL configuration.

Set up [autovacuum](#) on the PostgreSQL database. Note that, after pruning, a lot of dead tuples will need removing.

13.3.3 HTTP JSON API Service

We recommend using a relational database and dedicated compute resources to manage large ACS size when using the HTTP JSON API and refer the reader to the above considerations.

Tip: See the HTTP JSON API service documentation on [managing high load in the query store](#) and [server scaling and redundancy](#) for more information.

Chapter 14

Upgrading and Extending Daml Applications

Database schemas tend to evolve over time. A new feature in your application might need an additional choice in one of your templates. Or a change in your data model will make your application perform better. We distinguish two kinds of changes to a Daml model:

- A Daml model extension

- A Daml model upgrade

An *extension* adds new templates and data structures to your model, while leaving all previously written definitions unchanged.

An *upgrade* changes previously defined data structures and templates.

Whether extension or upgrade, your new code needs to be compatible with data that is already live in a production system. In the following sections, we'll show you how to extend your Daml model, and two ways to upgrade your Daml models, depending on your data transformation and downtime requirements.

14.1 Extending Daml Applications

Consider the following simple Daml model for carbon certificates:

```
module CarbonV1 where

template CarbonCert
  with
    issuer : Party
    owner  : Party
    carbon_metric_tons : Int
  where
    signatory issuer, owner
```

It contains two templates. The above template representing a carbon compensation certificate. And a second template to create the *CarbonCert* via a [Propose-Accept workflow](#).

Now we want to extend this model to add trust labels for certificates by third parties. We don't want to make any changes to the already deployed model. Changes to a Daml model will result in changed

package ID's for the contained templates. This means that if a Daml model is already deployed, the modified Daml code will not be able to reference contracts instantiated with the old package. To avoid this problem, it's best to put extensions in a new package.

In our example we call the new package *carbon-label* and implement the label template like

```
module CarbonLabel where

import CarbonV1

template CarbonLabel
  with
    cert : ContractId CarbonCert
    labelOwner : Party
  where
    signatory labelOwner
```

The *CarbonLabel* template references the *CarbonCert* contract of the *carbon-1.0.0* packages by contract ID. Hence, we need to import the *CarbonV1* module and add the *carbon-1.0.0* to the dependencies in the *daml.yaml* file. Because we want to be independent of the Daml SDK used for both packages, we import the *carbon-1.0.0* package as data dependency

```
name: carbon-label
version: 1.0.0
dependencies:
  - daml-prim
  - daml-stdlib
data-dependencies:
  - path/to/carbon-1.0.0.dar
```

Deploying an extension is simple: just upload the new package to the ledger with the *daml ledger upload-dar* command. In our example the ledger runs on the localhost:

```
daml ledger upload-dar --ledger-port 6865 --ledger-host localhost ./daml/dist/
↳ carbon-label-1.0.0.dar
```

If instead of just extending a Daml model you want to modify an already deployed template of your Daml model, you need to perform an upgrade of your Daml application. This is the content of the next section.

14.2 Upgrading Daml Applications

In applications backed by a centralized database controlled by a single operator, it is possible to upgrade an application in a single step that migrates all existing data to a new data model.

As a running example, let's imagine a centralized database containing carbon offset certificates. Its operator created the database schema with

```
CREATE TABLE carbon_certs (
  carbon_metric_tons VARINT,
  owner VARCHAR NOT NULL
  issuer VARCHAR NOT NULL
)
```

The certificate has a field for the quantity of offset carbon in metric tons, an owner and an issuer.

In the next iteration of the application, the operator decides to also store and display the carbon offset method. In the centralized case, the operator can upgrade the database by executing the single SQL command

```
ALTER TABLE carbon_certs ADD carbon_offset_method VARCHAR DEFAULT "unknown"
```

This adds a new column to the `carbon_certs` table and inserts the value `unknown` for all existing entries.

While upgrading this centralized database is simple and convenient, its data entries lack any kind of signature and hence proof of authenticity. The data consumers need to trust the operator.

In contrast, Daml templates always have at least one signatory. The consequence is that the upgrade process for a Daml application needs to be different.

14.2.1 Daml Upgrade Overview

In a Daml application running on a distributed ledger, the signatories of a contract have agreed to one specific version of a template. Changing the definition of a template, e.g., by extending it with a new data field or choice without agreement from its signatories would completely break the authorization guarantees provided by Daml.

Therefore, Daml takes a different approach to upgrades and extensions. Rather than having a separate concept of data migration that sidesteps the fundamental guarantees provided by Daml, *upgrades are expressed as Daml contracts*. This means that the same guarantees and rules that apply to other Daml contracts also apply to upgrades.

In a Daml application, it thus makes sense to think of upgrades as an *extension of an existing application* instead of an operation that replaces existing contracts with a newer version. The existing templates stay on the ledger and can still be used. Contracts of existing templates are not automatically replaced by newer versions. However, the application is extended with new templates. Then if all signatories of a contract agree, a choice can archive the old version of a contract and create a new contract instead.

14.2.2 Structure Upgrade Contracts

Upgrade contracts are specific to the templates that are being upgraded. But most of them share common patterns. Here is the implementation of the above `carbon_certs` schema in Daml. We have some prescience that there will be future versions of `CarbonCert`, and so place the definition of `CarbonCert` in a module named `CarbonV1`

```
module CarbonV1 where

template CarbonCert
  with
    issuer : Party
    owner  : Party
    carbon_metric_tons : Int
  where
    signatory issuer, owner
```

A `CarbonCert` has an issuer and an owner. Both are signatories. Our goal is to extend this `CarbonCert` template with a field that adds the method used to offset the carbon. We use a different name for the

new template here for clarity. This is not required as templates are identified by the triple (*Packageld*, *ModuleName*, *TemplateName*).

```
module CarbonV2 where

template CarbonCertWithMethod
  with
    issuer : Party
    owner  : Party
    carbon_metric_tons : Int
    carbon_offset_method : Text
  where
    signatory issuer, owner
```

Next, we need to provide a way for the signatories to agree to a contract being upgraded. It would be possible to structure this such that issuer and owner have to agree to an upgrade for each individual *CarbonCert* contract separately. Since the template definition for all of them is the same, this is usually not necessary for most applications. Instead, we collect agreement from the signatories only once and use that to upgrade all carbon certificates.

Since there are multiple signatories involved here, we use a [Propose-Accept workflow](#). First, we define an *UpgradeCarbonCertProposal* template that will be created by the issuer. This template has an *Accept* choice that the owner can exercise. Upon execution it will then create an *UpgradeCarbonCertAgreement*.

```
template UpgradeCarbonCertProposal
  with
    issuer : Party
    owner  : Party
  where
    signatory issuer
    observer  owner
    key (issuer, owner) : (Party, Party)
    maintainer key._1
    choice Accept : ContractId UpgradeCarbonCertAgreement
      controller owner
    do create UpgradeCarbonCertAgreement with ..
```

Now we can define the *UpgradeCarbonCertAgreement* template. This template has one *nonconsuming* choice that takes the contract ID of a *CarbonCert* contract, archives this *CarbonCert* contract and creates a *CarbonCertWithMethod* contract with the same issuer and owner and the *carbon_offset_method* set to unknown.

```
template UpgradeCarbonCertAgreement
  with
    issuer : Party
    owner  : Party
  where
    signatory issuer, owner
    key (issuer, owner) : (Party, Party)
    maintainer key._1
    nonconsuming choice Upgrade : ContractId CarbonCertWithMethod
      with
        certId : ContractId CarbonCert
      controller issuer
    do cert <- fetch certId
      assert (cert.issuer == issuer)
```

(continues on next page)

(continued from previous page)

```

assert (cert.owner == owner)
archive certId
create CarbonCertWithMethod with
  issuer = cert.issuer
  owner = cert.owner
  carbon_metric_tons = cert.carbon_metric_tons
  carbon_offset_method = "unknown"

```

14.2.3 Build and Deploy carbon-1.0.0

Let's see everything in action by first building and deploying carbon-1.0.0. After this we'll see how to deploy and upgrade to carbon-2.0.0 containing the CarbonCertWithMethod template.

First we'll need a sandbox ledger to which we can deploy.

```
$ daml sandbox --port 6865
```

Now we'll setup the project for the original version of our certificate. The project contains the Daml for just the CarbonCert template, along with a CarbonCertProposal template which will allow us to issue some coins in the example below.

Here is the project config.

```

name: carbon
version: 1.0.0
dependencies:
  - daml-prim
  - daml-stdlib
  - daml-script
source: .

```

Now we can build and deploy carbon-1.0.0.

```

$ cd example/carbon-1.0.0
$ daml build
$ daml ledger upload-dar --port 6865

```

14.2.4 Create carbon-1.0.0 Certificates

Let's create some certificates!

First, we run a setup script to create 3 users alice, bob and charlie and corresponding parties. We write out the actual party ids to a JSON file so we can later use them in Navigator.

```

$ cd example/carbon-1.0.0
$ daml script --dar .dar/dist/carbon-1.0.0.dar --script-name Setup:setup --ledger-
  host localhost --ledger-port 6865 --output-file parties.json

```

The resulting parties.json file will look similar to the following but the actual party ids will vary.

```

{
  "alice": "party-19a21501-ba87-47be-90a6-
    692dfeafe64a::12203977cedf2d394073b4c58036e047fcc590f7f2d61d82503df431473c4277fe70
    ",

```

(continues on next page)

(continued from previous page)

```
"bob": "party-7ecb1d67-1d20-4612-be67-  
↪b5741c86204d::12203977cedf2d394073b4c58036e047fcc590f7f2d61d82503df431473c4277fe70  
↪"  
"charlie": "party-fae6a574-9860-422a-9fd4-  
↪7ca2f7295e41::12203977cedf2d394073b4c58036e047fcc590f7f2d61d82503df431473c4277fe70  
↪"  
}
```

We'll use the navigator to connect to the ledger, and create two certificates issued by Alice, and owned by Bob.

```
$ cd example/carbon-1.0.0  
$ daml navigator server localhost 6865
```

We point a browser to <http://localhost:4000>, and follow the steps:

1. Login as alice:

1. Select Templates tab.
2. Create a *CarbonCertProposal* with Alice as issuer and Bob as owner and an arbitrary value for the `carbon_metric_tons` field. Note that in place of Alice and Bob, you need to use the party ids from the previously created `parties.json`.
3. Create a 2nd proposal in the same way.

2. Login as bob:

1. Exercise the *CarbonCertProposal_Accept* choice on both proposal contracts.

14.2.5 Build and Deploy `carbon-2.0.0`

Now we setup the project for the improved certificates containing the `carbon_offset_method` field. This project contains only the *CarbonCertWithMethod* template. The upgrade templates are in a third `carbon-upgrade` package. While it would be possible to include the upgrade templates in the same package, this means that the package containing the new *CarbonCertWithMethod* template depends on the previous version. With the approach taken here of keeping the upgrade templates in a separate package, the `carbon-1.0.0` package is no longer needed once we have upgraded all certificates.

It's worth stressing here that extensions always need to go into separate packages. We cannot just add the new definitions to the original project, rebuild and re-deploy. This is because the cryptographically computed package identifier would change. Consequently, it would not match the package identifier of the original *CarbonCert* contracts from `carbon-1.0.0` which are live on the ledger.

Here is the new project config:

```
name: carbon  
version: 2.0.0  
dependencies:  
  - daml-prim  
  - daml-stdlib
```

Now we can build and deploy `carbon-2.0.0`.

```
$ cd example/carbon-2.0.0  
$ daml build  
$ daml ledger upload-dar --port 6865
```

14.2.6 Build and Deploy carbon-upgrade

Having built and deployed `carbon-1.0.0` and `carbon-2.0.0` we are now ready to build the upgrade package `carbon-upgrade`. The project config references both `carbon-1.0.0` and `carbon-2.0.0` via the `data-dependencies` field. This allows us to import modules from the respective packages. With these imported modules we can reference templates from packages that we already uploaded to the ledger.

When following this example, `path/to/carbon-1.0.0.dar` and `path/to/carbon-2.0.0.dar` should be replaced by the relative or absolute path to the DAR file created by building the respective projects. Commonly the `carbon-1.0.0` and `carbon-2.0.0` projects would be sibling directories in the file systems, so this path would be: `../carbon-1.0.0/.daml/dist/carbon-1.0.0.dar`.

```
name: carbon-upgrade
version: 1.0.0
dependencies:
  - daml-prim
  - daml-stdlib
data-dependencies:
  - path/to/carbon-1.0.0.dar
  - path/to/carbon-2.0.0.dar
```

The Daml for the upgrade contracts imports the modules for both the new and old certificate versions.

```
module UpgradeFromCarbonCertV1 where
import CarbonV1
import CarbonV2
```

Now we can build and deploy `carbon-upgrade`. Note that uploading a DAR also uploads its dependencies so if `carbon-1.0.0` and `carbon-2.0.0` had not already been deployed before, they would be deployed as part of deploying `carbon-upgrade`.

```
$ cd example/carbon-upgrade
$ daml build
$ daml ledger upload-dar --port 6865
```

14.2.7 Upgrade Existing Certificates from carbon-1.0.0 to carbon-2.0.0

We start the navigator again.

```
$ cd example/carbon-upgrade
$ daml navigator server localhost 6865
```

Finally, we point a browser to <http://localhost:4000> and can start the carbon certificates upgrades:

1. **Login as alice**
 1. Select Templates tab.
 2. Create an `UpgradeCarbonCertProposal` with Alice as issuer and Bob as owner. As before, in place of Alice and Bob use the party ids from `parties.json`.
2. **Login as bob**
 1. Exercise the `Accept` choice of the upgrade proposal, creating an `UpgradeCarbonCertAgreement`.
3. **Login again as alice**

1. Use the `UpgradeCarbonCertAgreement` repeatedly to upgrade any certificate for which Alice is issuer and Bob is owner.

14.2.8 Further Steps

For the upgrade of our carbon certificate model above, we performed all steps manually via Navigator. However, if Alice had issued millions of carbon certificates, performing all upgrading steps manually becomes infeasible. It thus becomes necessary to automate these steps. We will go through a potential implementation of an automated upgrade in the [next section](#).

14.3 Smart Contract Upgrade

14.3.1 Overview

14.3.1.1 What is Smart Contract Upgrade (SCU)?

Smart Contract Upgrade (SCU) allows Daml models (packages in DAR files) to be updated on Canton transparently, provided some guidelines in making the changes are followed. For example, you can fix an application bug by uploading the DAR of the fixed package. This feature requires the minimum versions of LF 1.17 and Canton Protocol version 7. This section provides an overview of the SCU feature, while [The Smart Contract Upgrade Model in Depth](#) is a concise, technical description of the feature.

Smart Contract Upgrade (SCU) is a feature for Daml packages which enable authors to publish new versions of their templates while maintaining compatibility with prior versions, without any downtime for package users and existing contracts.

Package authors previously upgraded their packages by either:

- Providing a Daml workflow for upgrading contracts to the new version, and tell users of the old version to use the workflow to upgrade their old templates to the new versions.

- This requires communication with all package users, splits package users across the two versions during the migration, and may incur significant network cost. This approach is described [here](#).

- Uploading the new version of their application code to their participant, temporarily stopping workflows relating to the old version, and manually upgrading every old template on the participant to the new version by directly manipulating Canton's databases. This method is error-prone and requires some downtime for the participant.

Now, with SCU, any contract from the old package is automatically interpreted as the new version as soon as it is used in a new workflow that requires it. This feature is well-suited for developing and rolling out incremental template changes. There are guidelines to ensure upgrade compatibility between DAR files. The compatibility is checked at compile time, DAR upload time, and runtime. This is to ensure data backwards upgrade compatibility and forwards compatibility (subject to the guidelines being followed) so that DARs can be safely upgraded to new versions. It also prevents unexpected data loss at clients if a runtime downgrade occurs (e.g., a client is using template version 1.0.0 while the participant node has the newer version 1.1.0).

A general guideline for SCU is that additive application changes are allowed but items cannot be removed. A summary of the allowed changes in templates are:

- A template can add new `Optional` fields at the end of the list of fields;

A `record` datatype can add new optional fields at the end of the list of fields, and a `variant` or `enum` datatype can add new constructors at the end;

The `ensure` predicate can be changed and it is reevaluated at interpretation;

A choice signature can be changed by adding `Optional` parameters at the end;

The controller of a choice can be changed;

The observer of a choice can be changed

The body of a choice can be changed;

A new choice can be added to a template;

The implementation of an interface instance can be changed;

The following table summarizes the changes supported by SCU. Consult the sections below for additional information. For application updates that are not covered by SCU, consult the [Automating the Upgrade Process](#) section, which describes an upgrade tool for migrating contracts from an old version to a new version.

Daml Model Change	Scope	Covered by SCU?	Comments
Rename of Module	Template Definition	No	
Rename of Template	Template Definition	No	
Change of Field Type	Template Definition	No	
Change of Field Ordering	Template Definition	No	
Change of Field Name	Template Definition	No	
Change of Signatories	Template Definition	No	<p>A new template version needs to return the same signatory result for a persisted contract, otherwise the contracts cannot be used by an upgraded package (this fails at runtime).</p> <p>One can change the function that computes the signatories (for example to take into account new fields) when creating contracts.</p>
Change of	Template	No	<p>The key's type cannot be changed, like adding a new field in the record it contains.</p> <p>One can change the function that computes the key in the same way the function computing the signatories can be changed. A persisted contract can be used by an upgrade only if the result of the function does not change.</p>
Change of Observers	Template Definition	No	Same as template signatories
Change of Key Maintainers	Template Definition	No	Same as template signatories
Change of Ensure Predicate	Template Definition	Yes	Note that the Ensure is recalculated just before usage so any changes need to ensure that a V1 contract is still valid as a V2 contract.
Addition of New Definition Fields, Enum, and Variant Constructors	Template Definition	Yes, but they must be optional	
Deletion of Fields from Template	Template Definition	No	
Change of Choice Implementation	Template Definition	Yes	
Change in Choice Controller	Choice	Yes	

In this way, package authors can publish new package versions that improve contract functionality without requiring any error-prone migrations, without downtime, without requiring any additional network traffic, and without any extensive communication with downstream users.

With SCU, packages may now be referenced by either:

- the package ID
- the package name.

Package names are used to group versions of a package. Any two packages with the same package name must have distinct package versions.

Note:

When defining a Daml package, the `name` field of the package's `daml.yaml` is now used to specify the SCU package name.

The JSON API server is compatible with the smart contract upgrade feature by:

- Supporting package names for commands and queries;
- Allowing use of an optional `packageIdSelectionPreference` field to specify a preferred package ID to use;
- Requiring either a package ID or package name to be present to disambiguate the partially-qualified form of template/interface IDs.

Previously JSON API had supported partially qualified template IDs, (i.e. simply `<module>:<entity>`) as an interactive convenience which fails if there is more than one package with matching template names. Since this format was not supported for production use and does not work with SCU, it is now unavailable.

The Java and TypeScript codegen allow the use of package name and package ID (if needed).

PQS supports for this feature. PQS now supports the highly sought after feature of using package-name (specified in `daml.yaml`) instead of the more cumbersome package-id. When specifying a template/interface/choice name, simply substitute any package-id with the package-name (eg. now `register:DA.Register:Token`) instead of the old `deadbeefpackageidhex:DA.Register:Token` format. This applies to template filters and SQL queries (eg. via the `active()` function). These functions will always return all versions of a given identifier. Qualified name can be:

- fully qualified, e.g. `<package-name>:<module-path>:<template-name>`
- partially qualified, e.g. `<module-path>:<template-name>`

Qualified names cannot be ambiguous.

The PQS Read API now returns the package-name, package-id, and package-version for each contract instance, making it easy for users to determine and inspect different versions over time. To reconstruct the old experience (should you need to) of querying one specific version, use a filter predicate in the SQL.

```
SELECT *
FROM active('mypackage:My.App:MyTemplate')
WHERE package_id = 'deadbeefpackageidhex'
```

14.3.1.2 Requirements

Note that SCU is only available when the criteria below are met:

- Canton 2.10.x or above
- Daml LF Version 1.17 or above
- Canton Protocol Version 7 or above

There are instructions below on how to configure this setup. The sections below, unless explicitly stated otherwise, assume that this is the case.

To prevent unexpected behavior, this feature enforces a unique package name and version for each DAR being uploaded to a participant node. This closes a loophole where the participant node allowed multiple DARs with the same package name and version. For backward compatibility, this restriction only applies for packages compiled with LF \geq 1.17. If LF $<$ 1.15 is used, there can be several packages with the same name and version but this should be corrected; duplicate package names and versions are no longer supported.

14.3.1.3 Smart Contract Upgrade Basics

To upgrade a package the package author modifies their existing package to add new functionality, such as new fields and choices. When the new package is uploaded to a participant with the old version, the participant ensures that every modification to the model in the new version is a valid upgrade of the previous version.

To be able to automatically upgrade a contract or datatype, SCU restricts the kinds of changes that a new package version can introduce over its prior version.

For example, the simplest kind of data transformation that SCU supports is adding a field to a template.

Given the following first version of a template:

```
template IOU
with
  issuer: Party
  owner: Party
  value: Int
where
  signatory issuer
  observer owner
```

You can add a new field for currency:

```
template IOU
with
  issuer: Party
  owner: Party
  value: Int
  -- New field:
  currency: Optional String
where
  signatory issuer
  observer owner
```

With SCU, any new template fields must be optional - templates from the old version are automatically upgraded to new versions by setting the new field to `None`. This optional field requirement extends to all records in your package. Conversely, newer contracts with this field set to `None` can be automatically downgraded to previous versions of the template in workflows that have not yet been updated.

Automatic Data Upgrades and Downgrades

When extending data in a Daml model, SCU requires the old model to be representable in the new model. For extending a record, we can only add nullable (`Optional`) fields, so that old data can be represented by setting these fields to `None`. Similar constraints hold for Variants and Enums, which only allow adding constructors, with some other restrictions covered in [Continuing to Write Your Upgrades](#). This approach is inspired by [Protobuf](#) and Typescript's ability to ignore [excess fields](#) via `as`.

Automatic data upgrades occur in the following places:

Submissions to the Ledger API

When you submit a command, and provide only a package-name instead of a package-id, Canton will automatically upgrade (or downgrade) the payloads you give to the most recent version of the package that is uploaded on the participant. It will also use the most recent implementation of any choices you exercise directly through the Ledger API, by automatically upgrading/downgrading the choice argument. Choice result upgrading/downgrading is handled by Consuming Clients, as discussed later in this section. This behavior can be influenced by [the package preference](#).

Updates in a choice body

When Fetching a contract, the contract payload will be automatically upgraded/downgraded to match the version expected by the calling choice body, as compiled into the DAR. When Exercising a choice on a contract, the contract payload will be upgraded/downgraded to match the version of the choice expected by the calling choice body. This means that in a choice body, an exercised choice argument or return type is never upgraded/downgraded.

Consuming Clients (such as Daml Script, TypeScript/Java codegen)

When clients query the Ledger API for contracts, the returned event payload format matches the template originally used for generating the event (creating a contract/exercising a choice). It is the responsibility of these clients to upgrade/downgrade the payloads they receive to match what is expected downstream. The same applies to choice results. Daml Script, as well as TypeScript/Java codegen, does this for you to match the Ledger API response to the package versions they were run/built from.

14.3.1.4 Upgrading Across the Stack

These are all the components that interact with SCU, and how you as a user should be aware that they interact.

Canton

When considering the Canton ledger nodes, only the Canton participant node is aware of smart contract upgrading. The Canton domain nodes are only concerned with the protocol version which must be at least 7 to allow connected participants to use upgradable Daml packages.

Below, we provide a brief overview of the interactions with the participant node that have been adapted for supporting the smart contract upgrading feature starting with Canton 2.10:

DAR upload requests go through an additional validation stage to check the contained new packages for upgrade-compatibility with other packages previously uploaded on the participant.

Ledger API command submissions can be automatically or explicitly up/downgraded if multiple upgrade-supported (language version ≥ 1.17) packages exist for the same package-name. Ledger API streaming queries are adapted to support fetching events more generically, by package-name.

Code Generation

The Java and TypeScript CodeGen have been updated to perform upgrades on retrieved contracts, and now use package-names over package-ids for commands to the participant.

JSON API Server

To match the changes to the Ledger API, the JSON API similarly supports package-name queries and command submission.

PQS & Daml Shell

As of 2.10, PQS only supports querying contracts via package-name, dropping support for direct package-id queries. See [the PQS section](#) for more information and a work-around.

Daml Shell builds on top of PQS, so inherits this behavior.

Daml Script

Support for SCU is available in the opt-in LTS version of Daml Script.

This version acts as a drop-in replacement for the previous Daml Script, and enables support for upgrades on all queries and command submissions.

We also expose functions for more advanced interactions with upgrades, as well as to revert to the previous submission behavior.

Daml Compiler

The Daml compiler supports the `upgrades: configuration` field - every time `daml build` is invoked, it validates the current package for upgrade compatibility against the package specified in the `upgrades: field`.

Validation emits custom error messages for common upgrading mistakes, and warns the package author when upgrading a package in a potentially unsafe way. Note however that this validation cannot be complete, as upgrade validity depends on a participant's package store. The participant's DAR upload checks have the final say on upgrade validity.

14.3.1.5 Limitations

To allow SCU to minimize downtime, and multiple versions of a package to be active at once, we limit the types of transformations that can be performed on live data. Following are some data transformations that cannot be made using SCU upgrades:

- Renaming, removal, or rearrangement of fields in a template
- Conversion of records to variants and vice versa
- Moving templates/datatypes to other modules
- Upgrading interface and exception definitions
- Adding/removing an interface instance on a template

These restrictions are required to give a simple model of runtime upgrades, avoiding ambiguity and non-obvious side effects. If you require any of these types of changes, you may need to consider a redeployment with downtime, either using the approach suggested in [Rolling out backwards-incompatible changes](#) or using the existing upgrade procedure described in [here](#).

In this version of SCU, the following functionality has not yet been implemented, but may be implemented in future releases.

- A LF 1.17 templates cannot implement a LF 1.15 interface.
- Retroactive interface instances are not compatible with SCU upgrades. SCU allows instances to be changed in an upgrade. However, a new interface instance cannot be added to a template in an upgrade; it requires an offline migration.
- Daml Script does not support SCU or LF1.17, you must use Daml Script LTS.

There are further limitations with respect to managing the packages on a running ledger:

- Once a version of a package is uploaded to the ledger, it cannot be replaced or removed. If a package is uploaded by mistake it can only be overridden by uploading an even newer version. As a consequence of the above, if a record is extended by mistake with an optional field, that field must be part of all future versions.
- Package versions cannot be deleted, they can only be unvetted. As a good rule of thumb the highest version for each package name should be vetted.
- If, for whatever reason, a lower version of a package is vetted and preferred, that package version needs to be explicitly mentioned in the command submissions in the specific `package_id_selection_preference` field of the `grpc Commands` message.
- Participants that confirm and observe a certain transaction must have vetted the package version that is preferred by the submitting participant. If that is not the case, the transaction is rejected.
- The contract create events sent as part of the active contracts and transaction streams are always represented according to the template definition in the package version used at time of their creation.

14.3.2 The Programming Model by Example

14.3.2.1 Writing Your First Smart Contract Upgrade

Setup

We continue with the example introduced in [Smart Contract Upgrade Basics](#). Begin by defining the first (old) version of our package:

```
> mkdir -p v1/my-pkg
> cd v1/my-pkg
> daml init
> daml version
SDK versions:
  2.10.0 (project SDK version from daml.yaml)
```

Running `daml version` should print a line showing that 2.10.0 or higher is the project SDK version from `daml.yaml`.

Add `daml-script-lts` to the list of dependencies in `v1/my-pkg/daml.yaml`, as well as `--target=1.17` to the build-options:

```
...
name: my-pkg
...
dependencies:
- daml-prim
- daml-stdlib
- daml-script-lts
build-options:
- --target=1.17
```

Note: Throughout this tutorial we ignore some best practices in favor of simplicity. In particular, we recommend a package undergoing SCU should contain a version identifier in its name as well, but we omit this - consult the section on [package naming best practices](#) to learn more. We also recommend that you do not depend on `daml-script-lts` in any package that is uploaded to the ledger - more on this [here](#).

Then create `v1/my-pkg/daml/Main.daml`:

```
module Main where

import Daml.Script

template IOU
  with
    issuer: Party
    owner: Party
    value: Int
  where
    signatory issuer
    observer owner
    key issuer : Party
    maintainer key
```

Running `daml build` should successfully produce a DAR in `v1/my-pkg/.daml/dist/my-pkg-1.0.0.dar`:

```
> daml build
Running single package build of my-pkg as no multi-package.yaml was found.
...
Compiling my-pkg to a DAR.
...
Created .daml/dist/my-pkg-1.0.0.dar
```

Now you can create the second (new) version of this package, which upgrades the first version. Navigate back to the root directory and copy the v1 package into a v2 directory.

```
> cd ../../
> cp -r v1 v2
> cd v2/my-pkg
```

Edit the `daml.yaml` to update the package version, and add the `upgrades:` field pointing to v1:

```
version: 1.1.0
...
dependencies:
- daml-prim
- daml-stdlib
- daml-script-lts
upgrades: ../../v1/my-pkg/.daml/dist/my-pkg-1.0.0.dar
build-options:
- --target=1.17
```

Any changes you make to v2 are now validated as correct upgrades over v1.

Adding a New Field

Begin by adding a new `currency` field to `v2/my-pkg/daml/Main.daml`:

```
...
template IOU
  with
    issuer: Party
    owner: Party
    value: Int
    currency: Text -- New field
  where
...

```

Run `daml build`. An error is emitted:

```
> daml build
...
error type checking template Main.IOU :
  The upgraded template IOU has added new fields, but those fields are not
  Optional.
ERROR: Creation of DAR file failed.
```

Any new fields added to a template must be optional - old contracts from the previous version are automatically upgraded by setting new fields to `None`.

Fix the currency field to be optional, and re-run `daml build`:

```
...
  currency: Optional Text -- New field
...
```

```
> daml build
...
Created .daml/dist/my-pkg-1.0.0.dar
```

The build may produce warnings about expression changes - this is covered in the [Continuing to Write Your Upgrades](#) section.

Seeing Upgraded Fields in Contracts

Using the Daml Sandbox, we can see our old contracts automatically upgrade.

Add a script to make and get IOUs to `v1/my-pkg/daml/Main.daml`:

```
module Main where

import Daml.Script
...
mkIOU : Script Party
mkIOU = do
  alice <- allocateParty "alice"
  alice `submit` createCmd (IOU alice alice 1)
  pure alice

getIOU : Party -> Script (Optional (ContractId IOU), IOU)
getIOU key = queryContractKey @IOU key key
```

Open `v2/my-pkg/daml/Main.daml` and add scripts to make IOUs with and without a currency field, and a script to get any IOU:

```
module Main where

import Daml.Script
...
mkIOU : Script Party
mkIOU = do
  alice <- allocateParty "alice"
  alice `submit` createCmd (IOU alice alice 1 (Some "USD"))
  pure alice

mkIOUWithoutCurrency : Script Party
mkIOUWithoutCurrency = do
  alice <- allocateParty "alice"
  alice `submit` createCmd (IOU alice alice 1 None)
  pure alice

getIOU : Party -> Script (Optional (ContractId IOU), IOU)
getIOU key = queryContractKey @IOU key key
```

Start a new terminal, run `daml sandbox` to start a simple ledger in which to test upgrades.

```
> daml sandbox
Starting Canton sandbox.
Listening at port 6865
Canton sandbox is ready.
```

Start another terminal, separately from the terminal in which the sandbox is running. From inside `v1/my-pkg`, upload and run the `mkIOU` script and place the resulting party for Alice into an output file `alice-v1`:

```
> cd v1/my-pkg
> daml ledger upload-dar --port 6865
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.0.0.dar \
  --script-name Main:mkIOU \
  --output-file alice-v1
...
```

From inside `v2/my-pkg`, upload and run the `getIOU` script, passing in the `alice-v1` file as the script's input:

```
> cd ../../v2/my-pkg
> daml ledger upload-dar --port 6865
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.1.0.dar \
  --script-name Main:getIOU \
  --output-file /dev/stdout \
  --input-file ../../v1/my-pkg/alice-v1
...
{
  "_1": "...",
  "_2": {
    "issuer": "party-...",
    "owner": "party-...",
    "value": 1,
    "currency": null
  }
}
...
```

The returned contract has a field `currency` which is set to `null`. When running the `getIOU` script from `v1`, this field does not appear.

```
> cd ../../v1/my-pkg
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.0.0.dar \
  --script-name Main:getIOU \
  --output-file /dev/stdout \
  --input-file alice-v1
...
{
  "_1": "...",
  "_2": {
    "issuer": "party-...",
```

(continues on next page)

(continued from previous page)

```
"owner": "party-...",
"value": 1
}
}
...
```

Downgrading Contracts

New contracts cannot be downgraded if they have a value in their Optional fields. Create a new v2 IOU contract from the `v2/my-pkg` directory, with USD as currency:

```
> # Create a new v2 IOU contract, with USD as currency
> cd ../../v2/my-pkg
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.1.0.dar \
  --script-name Main:mkIOU \
  --output-file alice-v2
...
```

Query it from a v1 script in the `v1/my-pkg` directory:

```
> # Query from v1 package
> cd ../../v1/my-pkg
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.0.0.dar \
  --script-name Main:getIOU \
  --output-file /dev/stdout \
  --input-file ../../v2/my-pkg/alice-v2
...
Exception in thread "main" com.daml.lf.engine.script.Script$FailedCmd: Command
↳ QueryContractKey failed: Failed to translate create argument:
...
An optional contract field with a value of Some may not be dropped during
↳ downgrading.
```

The error states that the optional field may not be dropped during downgrading.

Contracts created in a workflow from a v2 package may be used if the optional, upgraded fields are set to `None`. For example, create an IOU with the currency field set to `None` using `mkIOUWithoutCurrency`:

```
> # Create a new v2 IOU contract, without USD as currency
> cd ../../v2/my-pkg
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.1.0.dar \
  --script-name Main:mkIOUWithoutCurrency \
  --output-file alice-v2
...
```

And then query it from v1:

```

> # Query from v1 package
> cd ../../v1/my-pkg
> daml script \
    --ledger-host localhost --ledger-port 6865 \
    --dar .daml/dist/my-pkg-1.0.0.dar \
    --script-name Main:getIOU \
    --output-file /dev/stdout \
    --input-file ../../v2/my-pkg/alice-v2
...
    "issuer": "party-...",
    "owner": "party-...",
    "value": 1
...

```

In this case, the query from v1 succeeded because all upgraded fields are set to None.

Adding a Choice

SCU also allows package authors to add new choices - add the example choice `Double` to `v2/my-pkg/daml/Main.daml`, which archives the current contract and produces a new one with twice the value.

```

...
    maintainer key
    choice Double : ContractId IOU
        controller issuer
        do create this with value = value * 2
...

```

Along with a script to call it.

```

import DA.Optional (fromSome)

...

doubleIOU : Party -> Script IOU
doubleIOU alice = do
    oIOU <- getIOU alice
    case oIOU of
        Some (cid, _) -> do
            newCid <- alice `submit` exerciseCmd cid Double
            fromSome <$> queryContractId alice newCid
        None -> fail "Failed to find IOU"

```

Compiled changes are checked against the previous version and pass:

```

> daml build
...
Compiling my-pkg to a DAR.
...
Created .daml/dist/my-pkg-1.1.0.dar
...

```

Restart the sandbox and re-upload both v1 and v2:

```
> cd v1/my-deps
> daml ledger upload-dar --port 6865
> # Make a new IOU
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.0.0.dar \
  --script-name Main:mkIOU \
  --output-file alice-v1
...
> cd ../../v2/my-deps
> daml ledger upload-dar --port 6865
...
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.1.0.dar \
  --script-name Main:doubleIOU \
  --output-file /dev/stdout \
  --input-file ../../v1/my-pkg/alice-v1
...
    "issuer": "party-...",
    "owner": "party-...",
    "value": 2,
    "currency": null
...

```

Contracts made in v1 can now be exercised with choices introduced in v2.

Exercising a v1 choice on a v2 contract is also possible if upgraded fields are set to `None`, but this requires a different script function - replace the use of `exerciseCmd` with `exerciseExactCmd` in the body of `doubleIOU` in v1, and restart your sandbox.

```
> # Replace exerciseCmd with exerciseExactCmd in v1
> # Do it using your editor, or use `sed`
> sed -i -E 's/exerciseCmd/exerciseExactCmd/g' \
  v1/my-pkg/daml/Main.daml

```

Once you've restarted your sandbox, create an IOU without a currency in V2 via `mkIOUWithoutCurrency`, then run `doubleIOU` on it from V1:

```
> # Create a new v2 IOU contract, without USD as currency
> cd v2/my-pkg
> daml ledger upload-dar --port 6865
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.1.0.dar \
  --script-name Main:mkIOUWithoutCurrency \
  --output-file alice-v2
> cd ../../v1/my-pkg
> daml ledger upload-dar --port 6865
> daml script \
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.0.0.dar \
  --script-name Main:doubleIOU \
  --output-file /dev/stdout \
  --input-file ../../v2/my-pkg/alice-v2
...

```

(continues on next page)

(continued from previous page)

```
"issuer": "party-...",  
"owner": "party-...",  
"value": 2  
...
```

Existing choices can also be upgraded, as covered in [Continuing to Write Your Upgrades](#).

14.3.2.2 Deploying Your First Upgrade

Configuring Canton to Support Smart Upgrading

When using the feature one must be using Protocol Version 7.

Using Smart Contract Upgrading Enabled Packages

Once you have finished development of your smart contract app, use the mentioned upgrade-enabled options in `daml.yaml` to compile and generate the related DAR. This can be uploaded using the existing gRPC endpoints without modifications and is immediately available for use.

Note: In 2.10, once a DAR is successfully uploaded, it cannot be safely removed from the participant node. Participant operators must then ensure that uploaded functionality does not break the intended upgrade lineage as newly uploaded DARs affect the upgrading line (i.e. all subsequent uploads must be compatible with this one as well).

Note: Upgrade-supported packages stored on the participant must lead to unique package-id -> (package-name, package-version) relationships since runtime package-name -> package-id resolution must be deterministic (see *Ledger API*). For this reason, once a LF 1.17+ DAR has been uploaded with its main package having a specific package-name/package-version, this relationship cannot be overridden. Hence, uploading a DAR with different content for the same name/version as an existing DAR on the participant leads to a rejection with error code `KNOWN_DAR_VERSION`.

Validate the DAR Against a Running Participant Node

Starting with 2.10 you can validate your DAR against the current participant node state without uploading it to the participant via the `PackageManagementService.validateDar` Ledger API endpoint. This allows participant node operators to first check the DAR before uploading it.

This operation is also available via the Canton Admin API and Console:

```
participant.dars.validate("dars/CantonExamples.dar")
```

Upgrading and Package Vetting

Upgradable packages are also subject to [package vetting restrictions](#): in to be able to use a package in Daml transactions with smart contract upgrading, it must be vetted by all participants informed about the transaction. This applies to both the packages used for creating the contracts and the target packages.

Note: Package vetting is enabled by default on DAR upload operations.

14.3.2.3 Continuing to Write Your Upgrades

SCU allows package authors to change many more aspects of their packages - fields can be extended in templates, choices, and data type definitions. Choice bodies can be changed, and other expressions such as key definitions and signatory lists can be changed with caveats.

Setup

Continue the package defined in the *Writing Your First Upgrade* section above, but overwrite the v1 and v2 IOU modules. The v1 IOU module should be overwritten as follows:

```
module Main where

import Daml.Script

template IOU
  with
    issuer: Party
    owner: Party
    value: Int
  where
    signatory issuer
    observer owner
    key issuer : Party
    maintainer key

mkIOU : Script Party
mkIOU = do
  alice <- allocateParty "alice"
  alice `submit` createCmd (IOU alice alice 1)
  pure alice

getIOU : Party -> Script (Optional (ContractId IOU, IOU))
getIOU key = queryContractKey @IOU key key
```

The v2 IOU module should be overwritten to look like the following:

```
module Main where

import Daml.Script
import DA.Optional (fromOptional)

template IOU
  with
```

(continues on next page)

(continued from previous page)

```

    issuer: Party
    owner: Party
    value: Int
    currency: Optional Text
  where
    signatory issuer
    observer owner
    key issuer : Party
    maintainer key

mkIOU : Script Party
mkIOU = do
  alice <- allocateParty "alice"
  alice `submit` createCmd (IOU alice alice 1 (Some "USD"))
  pure alice

mkIOUWithoutCurrency : Script Party
mkIOUWithoutCurrency = do
  alice <- allocateParty "alice"
  alice `submit` createCmd (IOU alice alice 1 None)
  pure alice

getIOU : Party -> Script (Optional (ContractId IOU), IOU)
getIOU key = queryContractKey @IOU key key

```

All other files should remain the same.

Changing Choices

Add the following choice, `Duplicate`, to both v1 and v2 versions of IOU:

```

data DuplicateResult = DuplicateResult with
  newCid : ContractId IOU

choice Duplicate : DuplicateResult
  controller issuer
  do
    cid <- create this with value = value * 2
    return DuplicateResult with newCid = cid

```

Running `daml build` should succeed without errors.

```

> cd v1/my-pkg
> daml build
...
Created .daml/dist/my-pkg-1.0.0.dar
> cd ../../v2/my-pkg
> daml build
...
Created .daml/dist/my-pkg-1.1.0.dar

```

Next, upgrade the `Duplicate` choice by adding an optional field `amount`, and changing the behavior of the choice to default to a multiple of 3. Also upgrade the `DuplicateResult` data type to include the old value. Replace the definitions of the `DuplicateResult` data type and of the `Duplicate`

choice in v2 only:

```
...
-- Add import to top of module
import DA.Optional (fromOptional)
...
-- Replace DuplicateResult definition
data DuplicateResult = DuplicateResult with
  newCid : ContractId IOU
  oldValue : Optional Int -- New optional oldValue field
...
-- Replace Duplicate choice implementation
choice Duplicate : DuplicateResult
  with
    amount : Optional Int -- New optional amount
  controller issuer
  do
    let amt = fromOptional 3 amount
    cid <- create this with value = value * amt
    return DuplicateResult with
      newCid = cid
      oldValue = Some value
...
```

Add a script called duplicateIOU in V1:

```
...
duplicateIOU : Party -> Script (Optional (ContractId IOU, IOU))
duplicateIOU key = do
  mbIOU <- getIOU key
  case mbIOU of
    None -> pure None
    Some (iouCid, _) -> do
      res <- key `submit` exerciseExactCmd iouCid Duplicate
      mbNewIOU <- queryContractId key res.newCid
      case mbNewIOU of
        Some newIOU -> pure (Some (newCid, newIOU))
        None -> pure None
```

A similar script called duplicateIOU should be added in V2, supplying an amount field:

```
...
duplicateIOU : Party -> Script (Optional (ContractId IOU, Int, IOU))
duplicateIOU key = do
  mbIOU <- getIOU key
  case mbIOU of
    None -> pure None
    Some (iouCid, _) -> do
      res <- key `submit` exerciseExactCmd iouCid Duplicate { amount = Some 4 }
      case res.oldValue of
        None -> pure None -- This should never happen
        Some oldValue ->
          mbNewIOU <- queryContractId key res.newCid
          case mbNewIOU of
            Some newIOU -> pure (Some (newCid, oldValue, newIOU))
            None -> pure None
```

Running the v1 duplicateIOU script with exerciseExactCmd always runs the v1 implementation

for the `Duplicate` choice, and likewise for `v2`.

Modifying Signatory Definitions

Other definitions can be changed, but warnings are emitted to remind the developer that the changes can be unsafe and need to be made with care to preserve necessary invariants.

Signatories and observers are one expression that can be changed. Importantly, SCU assumes that the new definition does not alter the computed values of the signatories. The computed value of the observers is allowed to change in one specific way: observers that are also signatories can be removed. Any other change to the computed value of the observers (losing a non-signatory observer, adding an observer) is not allowed.

For example, add a new field of `outside observers` to the `v2 IOU` template, and add them to the observer definition.

```
...
-- Add a new outsideObservers field
outsideObservers: Optional [Party]
where
  signatory issuer
-- Add outsideObservers to the observer definition
  observer owner, fromOptional [] outsideObservers
...
```

The new observer definition allows `v2` contracts and beyond to add new observers via the `outsideObservers` field. However, any existing contracts default to `None` for the `outsideObservers` field, so all existing contracts have the same observer list as before: the single owner.

In the case where a contract's signatories or observers change in during an upgrade/downgrade in a way that doesn't meet the constraints above, the upgrade, and thus full transaction, fails at runtime.

Modifying Key Expressions

Similarly, key expressions can be changed as long as they evaluate to the same value for existing contracts.

For example, `v2` can add a new field `alternative key` to the `v2 IOU` template, and use it instead of the default key when present.

```
...
-- Add a new alternativeKey field
alternativeKey: Optional Party
where
  key fromOptional issuer alternativeKey
...
```

All old contracts will default to using the `issuer`, and new contracts will use the `alternativeKey` field.

Upgrading Enums

Variants and enums can be extended using SCU, either by adding fields to an existing constructor, or by adding a new constructor to the end of the list.

Redefine the IOU package, overwriting the v1 and v2 sections similarly to the previous section. Overwrite the IOU package in both V1 and V2 with the following:

```
module Main where

import Daml.Script

template IOU
  with
    issuer: Party
    owner: Party
    value: Int
    currency: Currency
  where
    signatory issuer
    observer owner
    key issuer : Party
    maintainer key

data Currency
  = USD
  | GBP
  deriving (Show, Eq, Ord)

mkIOU : Script Party
mkIOU = do
  alice <- allocateParty "alice"
  alice `submit` createCmd (IOU alice alice 1 USD)
  pure alice

getIOU : Party -> Script (Optional (ContractId IOU, IOU))
getIOU key = queryContractKey @IOU key key
```

Instead of using `Text` for the currency field, here we use an enum data-type `Currency` with two constructors: `USD` and `GBP`.

Running `daml build` should succeed with no errors:

```
> cd v1/my-pkg
> daml build
...
Created .daml/dist/my-pkg-1.0.0.dar
> cd ../../v2/my-pkg
> daml build
...
Created .daml/dist/my-pkg-1.1.0.dar
```

When you want to extend our contract to support new currencies, you can add new entries to the end of our `Currency` enum.

```
...
```

(continues on next page)

(continued from previous page)

```
data Currency
  = USD
  | GBP
  | CHF -- Add a new currency type
deriving (Show, Eq, Ord)
...
```

Upgrades of extended enums from an old version to a new version always succeed. In the case of IOUs, a v1 IOU can always be interpreted as a v2 IOU because the constructors for its `currency` field are a subset of those in a v2 contract.

For example, create an IOU with USD via v1's `mkIOU` script, and query it via v2's `getIOU` script:

```
> cd v1/my-pkg
> daml script
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.0.0.dar \
  --script-name Main:mkIOU \
  --output-file alice-v1
...
> cd ../../v2/my-pkg
> daml script
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.1.0.dar \
  --script-name Main:getIOU \
  --output-file /dev/stdout \
  --input-file ../../v1/my-pkg/alice-v1
...
"issuer": "party-...",
"owner": "party-...",
"value": 1,
"currency": "USD"
...
```

Only constructors that are defined in both v1 and v2 can be downgraded from v2 to v1. Any constructor that does not exist in the v1 package fails to downgrade with a runtime error. In the case of our IOU, any CHF fails to downgrade, so any v2 contracts with a CHF currency cannot be used in v1 workflows.

For example, create a contract with CHF as its `currency` field via v2's `mkIOU` script. Attempting to query it via v1's `getIOU` script fails with a lookup error for the CHF variant.

```
> cd v2/my-pkg
> daml script
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.1.0.dar \
  --script-name Main:mkIOU \
  --output-file alice-v2
...
> cd ../../v1/my-pkg
> daml script
  --ledger-host localhost --ledger-port 6865 \
  --dar .daml/dist/my-pkg-1.0.0.dar \
  --script-name Main:getIOU \
  --output-file /dev/stdout \
  --input-file ../../v2/my-pkg/alice-v2
```

(continues on next page)

(continued from previous page)

```
...
Failed to translate create argument:
↳Lookup(NotFound(DataVariantConstructor(c1543a5c2b7ff03650162e68e03e469d1ecf9f546565d3809cdec2e0255ed902:Main
↳CHF)),
↳DataEnumConstructor(c1543a5c2b7ff03650162e68e03e469d1ecf9f546565d3809cdec2e0255ed902:Main
↳CHF)))
...
```

Upgrading Variants

Variants, also known as algebraic data types, are very similar to enums except that they also contain structured data.

For example, the following variant has two constructors, each with unique fields. Overwrite both v1 and v2 modules with the following source:

```
module Main where

data Shape
  = Circle
  | Polygon { sides : Int }
```

You can extend this variant in two ways. You can add a new constructor, similarly to enums. Modify the v2 module to add a new `Line` constructor with a `len` field:

```
module Main where

data Shape
  = Circle
  | Polygon { sides : Int }
  | Line { len : Numeric 10 } -- New line constructor
```

As before, building should succeed.

```
> cd v1/my-pkg
> daml build
...
Created .daml/dist/my-pkg-1.0.0.dar
> cd ../../v2/my-pkg
> daml build
...
Created .daml/dist/my-pkg-1.1.0.dar
```

You can also add a new field to a constructor, similarly to templates - for example, add a `sideLen` field to the `Polygon` constructor, to specify the lengths of the sides of the polygon.

```
data Shape
  = Circle
  | Polygon
    { sides : Int
    , sideLen : Numeric 10 -- New field
    }
  | Line { len : Numeric 10 }
```

Building this fails because the new `sideLen` field is non-optional.

```
> cd v2/my-pkg
> daml build
...
error type checking data type Main.Shape:
  The upgraded variant constructor Polygon from variant Shape has added a field.
ERROR: Creation of DAR file failed.
```

Making the new `sideLen` field optional fixes the error:

```
...
    , sideLen : Optional (Numeric 10) -- New field
...
```

```
> cd v2/my-pkg
> daml build
...
Created .daml/dist/my-pkg-1.1.0.dar
```

Limitations in Upgrading Variants

Upgrading variants has some limitations - because the `Circle` constructor has been defined without a field in curly braces, it cannot be upgraded with new fields.

```
...
-- Add a field where no fields existed
= Circle { radius : Optional (Numeric 10) }
...
```

```
> cd v2/my-pkg
> daml build
...
error type checking data type Main.Shape:
  The upgraded data type Shape has changed the type of a variant.
ERROR: Creation of DAR file failed.
```

The same applies to variants with unnamed fields. If the v1 definition of the `Line` constructor were as follows, it would also not be able to upgrade:

```
...
| Line (Numeric 10)
```

In general, in order to enable future upgrades, it is strongly recommended that all constructors use named fields, and that all constructors have at least one field. If a constructor has no fields in an initial v1 package, one can assign a dummy field.

For example, the correct way to write the v1 `Circle` constructor would be as follows:

```
...
= Circle { dummy : () }
...
```

The subsequent v2 upgrade would succeed:

```
...
= Circle { dummy : (), radius : Optional (Numeric 10) }
...
```

Nested Datatypes

If a data type, choice, or template has a field which refers to another data type, the larger data type can be upgraded if the field's data type is upgradeable.

For example, given the data type A with a field referring to data type B,

```
data A = A { b : B }
data B = B { field : Text }
```

If modifications made to B are valid for SCU, then A is also valid.

Dependencies

Package authors may upgrade the dependencies of a package as well as the package itself. A new version of a package may add new dependencies, and must have all the (non-*utility-package*) dependencies of the old version. If these dependencies are used in ways that are checked for upgrades, each existing dependency must be either unchanged from the old DAR or an upgrade of its previous version.

For example, given a dependencies folder containing v1, v2, and v3 of a dependency package dep:

```
> ls ./dependencies
dep-1.0.0.dar
dep-2.0.0.dar
dep-3.0.0.dar
```

Then assume a version 1.0.0 of a package `main` that depends on a datatype from version 2.0.0 of `dep`:

```
module Main where

import qualified Dep

data MyData = MyData
  { depData : Dep.AdditionalData
  }
```

```
...
dependencies:
- daml-prim
- daml-stdlib
- daml3-script
data-dependencies:
- dependencies/dep-2.0.0.dar
...
```

Because a package with a newer version may upgrade any dependency to a newer version (or keep the version the same), version 2.0.0 of the main package may keep its dependencies the same, or it may upgrade dep to 3.0.0:

```
...
dependencies:
- daml-prim
- daml-stdlib
- daml3-script
data-dependencies:
- dependencies/dep-3.0.0.dar # Can upgrade dep-2.0.0 to dep-3.0.0, or leave it
  ↪ unchanged
...
```

You cannot downgrade a dependency when using that dependency's datatypes. For example, main may not downgrade dep to version 1.0.0. The following daml.yaml would be invalid:

```
...
dependencies:
- daml-prim
- daml-stdlib
- daml3-script
data-dependencies:
- dependencies/dep-1.0.0.dar # Cannot downgrade dep-2.0.0 to dep-1.0.0
...
```

If you try to build this package, the typechecker returns an error on a package ID mismatch for the Dep:AdditionalData field, because the Dep:AdditionalData reference in this case has changed to a package that is not a legitimate upgrade of the original.

```
> daml build
...
error type checking data type Main.MyData:
The upgraded data type MyData has changed the types of some of its original
  ↪ fields:
    Field 'depData' changed type from <dep-2.0.0 package ID>:Dep:AdditionalData to
  ↪ <dep-1.0.0 package ID>:Dep:AdditionalData
```

Upgrading Interface Instances

SCU also supports changing Interface instances. First, create a new package directory my-iface, with my-iface/daml.yaml and module my-iface/daml/MyIface.daml:

```
sdk-version: 2.10.0
name: my-iface
version: 1.0.0
source: daml/MyIface.daml
parties:
- Alice
- Bob
dependencies:
- daml-prim
- daml-stdlib
build-options:
- --target=1.17
```

```
module MyIface where

data HasValueView = HasValueView { hasValueView : Int }

interface HasValue where
  viewtype HasValueView
  getValue : Int
```

And build the module:

```
> cd my-iface
> daml build
...
Created .daml/dist/my-iface-1.0.0.dar
```

Add references to the newly created DAR in both `v1/my-pkg/daml.yaml` and `v2/my-pkg/daml.yaml`:

```
...
dependencies:
- daml-prim
- daml-stdlib
- daml3-script
- ../../my-iface/.daml/dist/my-iface-1.0.0.dar
...
```

Overwrite both `v1/my-pkg/daml/Main.daml` and `v2/my-pkg/daml/Main.daml` with the following:

```
module Main where

import Daml.Script
import MyIface

template IOU
  with
    issuer: Party
    owner: Party
    value: Int
  where
    signatory issuer
    observer owner
    key issuer : Party
    maintainer key

    interface instance HasValue for IOU where
      view = HasValueView value
      getValue = value
```

Interface instances can be changed by an upgrade. For example, `v2` can change the definition of `getValue` in the `HasValue` instance.

Add a `quantity` field to the `v2 IOU` package, and amend the definition of `getValue` to use it:

```
...
import DA.Optional (fromOptional)
```

(continues on next page)

(continued from previous page)

```

template IOU
  with
    issuer: Party
    owner: Party
    value: Int
    quantity: Optional Int -- new quantity field
  where
...
  interface instance HasValue for IOU where
    view = HasValueView (value * fromOptional 1 quantity)
    -- Use quantity field to calculate value
    getValue = value * fromOptional 1 quantity

```

Shut down and relaunch the Daml sandbox, then build and upload the two DARs. They should both succeed again:

```

> cd v1/my-pkg
> daml build
> daml ledger upload-dar --port 6865
...
Uploading .daml/dist/my-pkg-1.0.0.dar to localhost:6865
DAR upload succeeded.
> cd ../../v2/my-pkg
> daml build
> daml ledger upload-dar --port 6865
...
Uploading .daml/dist/my-pkg-1.1.0.dar to localhost:6865
DAR upload succeeded.

```

Packages with new versions cannot remove an instance that is already there. For example, the v2 IOU template cannot remove its instance of `HasValue`. Comment out the interface instance for `HasValue` from `v2/my-pkg/daml/Main.daml` completely, then restart the sandbox and try to reupload the two versions:

```

> cd v1/my-pkg
> daml build
> daml ledger upload-dar --port 6865
...
Uploading .daml/dist/my-pkg-1.0.0.dar to localhost:6865
DAR upload succeeded.
> cd ../../v2/my-pkg
> daml build
> daml ledger upload-dar --port 6865
...
Uploading .daml/dist/my-pkg-2.0.0.dar to localhost:6865
upload-dar did not succeed: ... Implementation of interface ...:MyIface:HasValue
↳by template IOU appears in package that is being upgraded, but does not appear
↳in this package.

```

Packages with new versions cannot add an interface instance to an existing template either. For example, restore the instance deleted in the previous step and remove the `HasValue` interface from `v2/my-pkg/daml/Main.daml` instead. Then restart the sandbox and try to reupload the two versions.

```
> cd v1/my-pkg
> daml build
> daml ledger upload-dar --port 6865
...
Uploading .daml/dist/my-pkg-1.0.0.dar to localhost:6865
DAR upload succeeded.
> cd ../../v2/my-pkg
> daml build
> daml ledger upload-dar --port 6865
...
Uploading .daml/dist/my-pkg-2.0.0.dar to localhost:6865
upload-dar did not succeed: ... Implementation of ...:MyIface:HasValue by
↳ template IOU appears in this package, but does not appear in package that is
↳ being upgraded.
```

Similarly to choices, scripts may invoke interface implementations from their own version using `exerciseExactCmd`.

Upgrading Interfaces

Interface instances may be upgraded, but interface definitions cannot be upgraded. If an interface definition is present in v1 of a package, it must be removed from all subsequent versions of that package.

Because interfaces definitions may not be defined in subsequent versions, any package that uses an interface definition from a dependency package can never upgrade that dependency to a new version.

For this reason, it is *strongly recommended that interfaces always be defined in their own packages separately from templates*.

14.3.2.4 Developer Workflow

This section contains suggestions on how to set up your development environment for SCU to help you iterate more quickly on your projects.

Multi-Package Builds

Following the *best practices* outlined below and the *testing recommendations* leads to a proliferation of packages in your project. Use *Multi-Package builds* to reliably rebuild these packages as you iterate on your project. Multi-package builds also enable cross-package navigation in Daml Studio.

The *Multi-package builds for upgrades* section goes into more detail on how to set up multi-package builds for SCU and how it can help with testing.

Working with a Running Canton Instance

With SCU, it is no longer possible to iterate on a package by uploading it to a running participant after each rebuild. A participant rejects two packages with the same name and version whose content differs.

There are two ways to work around this:

- restart the participant after each rebuild
- change the version name of the package before each rebuild

[Environment variable interpolation](#) in the Daml Assistant can help with the latter. In the `daml.yaml` file of each of your packages, append an environment variable to the name of the package:

```
name: my-package-v${UNIQUE_BUILD_ID}
```

Make sure to also append the variable to the name of the DAR file produced by `my-package` in the `daml.yaml` files that depend on it:

```
dependencies:
- daml-prim
- daml-stdlib
data-dependencies:
- ../my-package/.daml/dist/my-package-${UNIQUE_BUILD_ID}.dar
```

Then, before invoking `daml build --all`, increment the `UNIQUE_BUILD_ID` environment variable. This ensures that the build produces unique DAR files that can be uploaded to the participant without conflict.

Working with the Daml Sandbox

For the same reason, the [Daml sandbox](#) does not support hot-swapping of SCU-enabled (LF 1.17) packages.

There are two ways to work around this:

- restart the sandbox after each rebuild
- change the version name of your packages after each rebuild, as outlined in the previous section

14.3.2.5 The Upgrade Model in Depth - Reference

You can find the in-depth upgrading model, which can be used as a reference for valid upgrades, [here](#).

14.3.3 Package Selection in the Ledger API

Until the introduction of SCU, template IDs in requests to the Ledger API were all of the form `<package-id>:<module-name>:<template-name>`. For disambiguation, going forward, we refer to this format as **by-package-id template IDs**.

With SCU, we introduce a more generic template reference of the format `#<package-name>:<module-name>:<template-name>` (**by-package-name template ID**) that scopes templates by package-name, allowing version-agnostic addressing of templates on the Ledger API. It serves as a reference to all template IDs with the qualified name

`<module-name>:<template-name>` from all packages with the name `package-name` known to the Ledger API server.

By-package-name template ID addressing is supported for all upgradable packages (LF \geq 1.17) and is possible on both the write path (command submission) and read path (Ledger API queries).

The *by-package-name template ID* is an API-level concept of the Ledger API. Internally, Canton uses *by-package-id template IDs* for all operations. Therefore, when the new format is used in requests to the Ledger API, a dynamic resolution is performed as described in the following sections.

14.3.3.1 Package Preference

On processing a command submission, there are scenarios where the Ledger API server needs to resolve *by-package-name template IDs* to *by-package-id template IDs* (see [Dynamic Package Resolution in Command Submission](#)). For this purpose, the **package preference** concept is introduced as the mapping from package-name to package ID for all known package-names on the participant.

The package preference is needed at each command submission time and is assembled from two sources:

The **default** package preference of the Ledger API server to which the command is submitted. This is the exhaustive mapping from package-name to package ID for all known package-names on the participant. If multiple package IDs exist for a package-name, the package ID of the package with the highest version is used.

The package-id selection preference list specified in the submitted command's [package_id_selection_preference](#) in a command submission. This is package-id resolution list explicitly provided by the client to override the default package preference mentioned above.

- See [here](#) for how to provide this in Daml-Script
- **Note:** The [package_id_selection_preference](#) must not lead to ambiguous resolutions for package-names, meaning that it must not contain two package-ids pointing to packages with the same package-name, as otherwise the submission will fail with an `INVALID_ARGUMENT` error.

Note: Important: DAR uploads change the package preference on the participant. If a new uploaded DAR contains an upgradable (LF \geq 1.17) package with a higher version than the existing package preference for the same package name, the default preference is updated to the new package ID. Essentially, this affects the Daml code version used in command submissions.

14.3.3.2 Dynamic Package Resolution in Command Submission

Dynamic package resolution can happen in two cases during command submission:

For command submissions that use a *by-package-name template ID* in the command's `templateId` field (e.g. in a `create` command [here](#))

For command submissions whose Daml interpretation requires the execution of interface choices or `fetch-by-interface` actions.

In these situations, the [package preference](#) is used for selecting the target implementation package for these interface actions.

14.3.3.3 Dynamic Package Resolution in Ledger API Queries

When subscribing for [transaction](#) or [active contract streams](#), users can now use the *by-package-name template ID* format in the [template-id request filter field](#) to specify that they're interested in fetching events for all templates pertaining to the specified package-name. This template selection set is dynamic and it widens with each uploaded template/package.

Note: The by-package-name query mechanism described here does not apply to events sourced from non-upgradable templates (coming from packages with LF < 1.17)

Example

Given the following packages with LF 1.17 existing on the participant node:

```
Package AppV1
- package-name: app1
- package-version: 1.0.0
- template-ids: pkgId1:mod:T
Package AppV2
- package-name: app1
- package-version: 1.1.0
- template-ids: pkgId2:mod:T
```

If a transaction query is created with a `templateId` specified as `#app1:mod:T`, then the events stream will include events from both `template-ids: pkgId1:mod:T` and `pkgId2:mod:T`

14.3.4 Migrating to SCU

SCU is only supported on LF1.17, which in turn is only supported on Canton Protocol Version 7. Existing deployed contracts require migration and redeployment to use this feature. See [here](#) for the migration guide to 2.10 and Protocol Version 7

First you must migrate your Daml model to be compatible with upgrades; see [Best Practices](#) for what to change here. Pay particular attention to the case of interfaces and exceptions, as failure to do so could lead to packages which are incompatible with SCU and require the use of another full migration (and downtime).

Next, be aware of the new package-name scoping rules, and ensure that your package set does not violate them. In short, LF1.17 packages with the same package name are unified under SCU, so you should ensure that all of your packages that are not intended to be direct upgrades of each other have unique package names. Note also that only one package for each version can exist within a given package name. LF1.15 packages are not subject to this restriction, and can exist alongside LF1.17 packages.

Once you have your new DARs, you need to upgrade your Canton and protocol version together, since 2.10 introduces a new protocol version. The steps to achieve this are given in the [Canton Upgrading manual](#).

Finally, you can migrate your live data from your previous DARs to the new LF1.17 DARs, using one of the existing downtime upgrade techniques listed [here](#).

14.3.5 Best Practices

To ensure that future upgrades and DAR lifecycling go smoothly, we recommend the following practices:

14.3.5.1 Separate Interfaces/Exceptions from Templates

Interface and exception definitions are not upgradable. As such, if you attempt to redefine an interface or exception in version 2 of a package, even if it is unchanged, the package does not type check. Removing an interface from the version 2 package also causes issues, especially if the interface has choices.

This means that template definitions that exist in the same package as interfaces and exception definitions are not upgradeable. To avoid this issue, move interface and exception definitions into a separate package such that subsequent versions of your template package all depend on the same version of the package with interfaces/exceptions.

For example, a single package `main` defined as follows would not be able to upgrade, leaving the template `T` non-upgradeable.

```
module Main where

interface I where
  ...

template T with
  ...
```

```
sdk-version: 2.10.0
name: main
version: 1.0.0
source: Main.daml
dependencies:
- daml-prim
- daml-stdlib
build-options:
- --target=1.17
```

The SCU type checker emits an error and refuses to compile this module:

```
error type checking <none>:
  This package defines both interfaces and templates. This may make this package
  ↪and its dependents not upgradeable.

  It is recommended that interfaces are defined in their own package separate
  ↪from their implementations.
  Downgrade this error to a warning with -Wupgrade-interfaces
  Disable this error entirely with -Wno-upgrade-interfaces
```

Note: It is very strongly recommended that you do not compile interfaces or exceptions in a package alongside templates. However, you can downgrade this error to a warning by passing the `-Wupgrade-interfaces` flag, or ignore this error entirely with the `-Wno-upgrade-interfaces` flag.

The recommended way to fix this is to split the `main` package by redefining it as two packages, `helper` and `main`:

```
module Helper where

interface I where
  ...
```

```
sdk-version: 2.10.0
name: helper
version: 1.0.0
source: Helper.daml
dependencies:
- daml-prim
- daml-stdlib
build-options:
- --target=1.17
```

```
module Main where

import qualified Helper

template T with
  ...
```

```
sdk-version: 2.10.0
name: main
version: 1.0.0
source: Main.daml
dependencies:
- daml-prim
- daml-stdlib
data-dependencies:
- <path to helper DAR>
build-options:
- --target=1.17
```

To manage the complexity of working with multiple packages at once, we recommend using [multi-package builds](#).

14.3.5.2 Remove Retroactive Instances

SCU is not compatible with retroactive interface instances, so if you are migrating to SCU from an LF1.15 project that uses retroactive instances, you must move the instances to their respective templates during the migration. See [Limitations](#) for more information.

14.3.5.3 Avoid Contract Metadata Changes

The signatories, stakeholders, contract key, and ensure clauses of a contract should be fixed at run-time for a given contract. Changing their definitions in your Daml code is discouraged and triggers a warning from the SCU typechecker.

We strongly recommend against altering the type of a key. If changing the type of a key cannot be avoided, consider using an off-ledger migration instead of SCU.

14.3.5.4 Breaking Changes via Explicit Package Version

To make a breaking change to your package that is not upgrade compatible, you can change the name of your package to indicate a breaking version bump. To enable this, we recommend that your package name contains a version marker for when a breaking change occurs.

For example, for your first iteration of a package, you would name it `main-v1`, starting with package version `1.0.0`. In this case, the `v1` is part of the package name, not the package version. You could publish upgrade-compatible versions by changing the `version:` field from `1.0.0` to `2.0.0` to `3.0.0`. These versions would all be upgrade-compatible with one another:

```
main-v1-1.0.0
main-v1-2.0.0
main-v1-3.0.0
```

Note how the `v1` in all three packages remains stable - this means the package name has not changed, and ensures that these three packages and their datatypes are considered by the runtime and the type checker to be upgradeable.

To make a breaking change, publish a new package version with package name `main-v2`. Because this package has a different package name from those with `main-v1`, it is not typechecked against those packages and its datatypes are not automatically converted. You would need to manually migrate values from `main-v1` packages to `main-v2` - existing downtime upgrade techniques are listed [here](#).

14.3.5.5 Avoid Depending on LF 1.15 Packages

Smart contract upgrades were only enabled in LF 1.17. This means that packages of previous LF versions, namely \leq LF 1.15, are not upgradeable. By extension, their datatypes and templates are not upgradeable.

This means that datatypes in an LF 1.17 package with fields that use datatypes from an LF 1.15 dependency cannot ever upgrade those datatypes, so that package remains a dependency forever.

As an example, assume we have three packages: `*main`, which uses LF 1.17, with module `Main` * `dep1`, which uses LF 1.15, with module `Dep1` * `dep2`, which uses LF 1.17, with module `Dep2`

```
module Main where

import qualified Dep1
import qualified Dep2

data MyData = MyData
  { field1: Dep1.D
```

(continues on next page)

(continued from previous page)

```
, field2: Dep2.D
, field3: (Dep1.D, Dep2.D)
}
```

Because datatype `Dep1.D` comes from an LF 1.15 dependency, it cannot be upgraded, and so `field1` and the second element of `field3` can never be changed. However, `field2` and the first element of `field3` can be upgraded as new upgraded versions of `dep2` become available.

If you compile `main`, you can expect a warning about the use of an LF 1.15 package's datatype in the definition of `MyData`.

```
> daml build
...
warning while type checking data type Main.MyData:
  This package has LF version 1.17, but it depends on a serializable type <dep1
  ↳ package ID>:Dep1:D from package <dep 1 package ID> (dep1, 1.0.0) which has LF
  ↳ version 1.15.

  We do not recommend that >= LF1.17 packages depend on <= LF1.15 datatypes in
  ↳ places that may be serialized to the ledger, because those datatypes are not
  ↳ upgradeable.
  Upgrade this warning to an error -Werror=upgrade-serialized-non-upgradeable-
  ↳ dependency
  Remove this warning with -Wno-upgrade-serialized-non-upgradeable-dependency
```

Note: For added safety, you may upgrade these warnings to errors with `-Werror=upgrade-serialized-non-upgradeable-dependency`. We recommend against removing these warnings with `-Wno-upgrade-serialized-non-upgradeable-dependency`.

14.3.5.6 Avoid Depending on Daml Script Packages

We recommend only depending on Daml Script packages such as `daml-script-lts` in dedicated packages for running tests written in Daml Script. These packages should not be part of your model and should not be uploaded to the ledger.

Daml Script packages are not guaranteed to be upgradeable across SDK versions. If you depend on a Daml Script datatype in a serializable position (e.g. the field of a template), your package may rely on a Daml Script package in a way that can neither be removed nor upgraded to the next SDK version. Your package and any of its SCU upgrades would be stuck on that SDK version.

For example, suppose you have a `main` package that depends on `daml-script-lts` from SDK 2.10.0.

```
version: 2.10.0
name: main
...
dependencies:
- daml-prim
- daml-stdlib
- daml-script-lts
build-options:
- --target=1.17
```

```
module Main where

import qualified Daml.Script

data MyData = MyData
  { field1 : Daml.Script.PartyIdHint
  }
```

Because `MyData` is a serializable datatype, any changes to it must be valid upgrade changes (e.g. adding a field) for the `main` package itself to be upgraded. If SDK 2.10.X introduces a change to `daml-script-lts` that is not a valid upgrade of the `daml-script-lts` in SDK 2.10.0, then `field1` is not upgradeable to the next version of the SDK, nor can the field be dropped because the field is used in SCU checks.

Note: While it is unlikely that an SDK update breaks `daml-script-lts` for upgrades, we still strongly recommend against it. In Daml 3.x, Canton may disallow uploading `daml-script-lts` entirely.

At that point, all future development on `main`, including future upgrades, would be locked to SDK 2.10.0. To bump the SDK version, `main` would have to be migrated via a manual upgrade tool with downtime – existing downtime upgrade techniques are listed [here](#).

For this reason, we strongly recommend against using Daml Script as an upgrade dependency for any package going on the ledger. Whenever building the `main` package above, you can expect a warning:

```
> daml build
...
warning while type checking data type Main.MyData:
  This package depends on a datatype <package ID>:Daml.Script.Stable:PartyIdHint
  ↳from <package ID> (daml-script-lts-stable, 0.0.0) with LF version 1.17.

  We do not recommend using datatypes from Daml Script in >= LF1.17 packages,
  ↳because those datatypes are not upgradeable.
  Upgrade this warning to an error -Werror=upgrade-serialized-daml-script
  Remove this warning with -Wno-upgrade-serialized-daml-script
```

Note: For added safety, you may upgrade these warnings to errors with `-Werror=upgrade-serialized-daml-script`. We recommend against removing these warnings with `-Wno-upgrade-serialized-daml-script`.

If instead `main` depends on a datatype in a non-serializable position such as the type signature of a function, `main` can still be upgraded without breaking any SCU restrictions. For example:

```
module Main where

import qualified Daml.Script

data MyData = MyData
  { field1 : Text
  }

myFunction : Daml.Script.PartyIdHint -> Bool
myFunction _ = True
```

In this case, when changing SDK from 2.10.0 to 2.10.X, the typechecker ignores the change to `Daml`.

`Script.PartyIdHint` in `myFunction`, because it is not in a serializable position. This means `daml-script-lts` can be kept even when it is not a valid upgrade from one version to the next.

Note: We still recommend against depending on Daml Script for ledger-uploaded packages, even in this case with non-serializable positions.

14.3.5.7 Operational Design Guideline for Upgrading Daml Apps

When considering upgrading, we regard each Daml application as composed of:

On-ledger components: The Daml code running the on-ledger logic (i.e. the DARs uploaded to all participant nodes interacting with the app)

Off-ledger components interacting with the ledger via the Ledger API or other supported Canton Ledger API clients (JSON API or PQS). These are typically Java or TypeScript services implementing off-ledger business logic.

Zero-Downtime Upgrades

Upgrading an application without operational downtime can be achieved by designing the above-mentioned components to allow:

Asynchronous rollout: Operators deploy updated software at their own pace, similar to established CI/CD practices in micro-service environments.

Synchronous switch-over: All components switch to using updated Daml code at the same time.

Designing for asynchronous upgrade roll-outs

To allow for asynchronous roll-outs, off-ledger components should:

use package names in Ledger API requests: App components interacting with the Ledger API should use *by-package-name template IDs* instead of *by-package-id template IDs* in all their command submissions and queries. This allows:

- Ledger API server-side version selection of the package preference for command submissions.
- reading all versions of the templates in queries, even newer versions than the one the component was developed against.

handle missing optional fields: App components reading from the Ledger API or Ledger API clients must be prepared to handle missing optional fields in records, including those in the initial package. The TypeScript and Java codegens for reading Daml values do so by default.

use exhaustive package preference: on each command submission, the `package_id_selection_preference` is set ensuring that:

- The package ID of every package used in the command and of every package used by all possible interface instances is included in the package preference.
- Within an application, all submissions use the same package preference.

Note: Following these recommendations decouples the application's behavior from the DAR uploads (see [the note regarding Package Preference](#)), as package resolution is fully determined by the explicit and exhaustive package preference provided in command submissions.

Operational steps for upgrading

Once a new Daml package version of the application is ready, define an operational window for allowing the asynchronous rollout of the updated components. During this window, Canton node and off-ledger app operators should:

- Upload the upgraded DARs to the participant nodes
- Roll-out the updated off-ledger components

After the operational window passes, the application can switch over to the upgraded logic as such:

A switch-over time is decided and communicated to all app clients in advance, along with the updated package preference pertaining to the application's upgraded DARs. For example, you may encode the switch-over time in a config value set on all components; or publish it at a well-known HTTP endpoint from which all components read it.

After the switch-over time, all Ledger API clients update their package preference and use it for subsequent command submissions.

Note: Ledger API clients or participant nodes that do not finish the components rollout before the update switch-over time may not be able to participate in the upgraded workflow.

Rolling out backwards-incompatible changes

Some changes to a Daml workflow cannot be made backwards-compatible, such as changing the definition of a template in a breaking way (e.g., extending the observer set).

To handle such changes, you can replace the existing contract with an upgraded one of the target template as follows:

Introduce the target template as a new template following the [Breaking changes via Explicit Package Version](#)

Add a consuming `OriginalTemplate_UpgradeToNewTemplate` choice to the existing template by rolling out a new version in a backwards-compatible fashion.

Where required, provide reference data for the `upgrade` choice via additional choice arguments.

Implement backend automation or a contract migration tool similar to the one described [here](#) to migrate all old contracts to the new ones by exercising the `upgrade` choice on the existing contracts.

Note: Rolling out backwards-incompatible changes as described in this section incurs downtime on affected workflows until their contracts have been converted by the automation. In order to not disrupt business, such rollouts should be executed during maintenance windows.

Note: Note that this kind of upgrade requires $O(\text{number-of-active-contracts})$ of transactions to roll out. Depending on the size of your ACS this can take a long time and consume significant compute and storage resources. In contrast, the backwards-compatible upgrades can be rolled out with constant cost, independent of the size of your ACS.

14.3.6 Testing

14.3.6.1 Standalone Upgradeability Checks

We recommend using the `upgrade-check` tool to perform a standalone check that all of the DARs typecheck against one another correctly as further validation of your upgraded packages.

This tool takes a list of DARs and runs Canton's participant-side upgrade typechecking without spinning up an instance of Canton. You should pass the tool the list of DARs constituting your previous model and the list of DARs for your new model.

For example, assume you have a helper package `helper` that does not change, and two packages `main` and `dep`.

```
main-1.0.0.dar
dep-1.0.0.dar
helper-1.0.0.dar
```

After upgrading your model, you would publish a new DAR `main-2.0.0.dar` for `main` and a new DAR `dep-2.0.0.dar` for `dep`. We would then recommend running the `upgrade-check` tool as follows:

```
> daml upgrade-check --participant helper-1.0.0.dar dep-1.0.0.dar main-1.0.0.dar
↪dep-2.0.0.dar main-2.0.0.dar
...
```

This runs the same upload validation over these DARs that would be run in the event of an upload to the ledger, and prints out the same messages and errors. Because it does not require a ledger to be spun up, the command runs much more quickly.

We can also check that all of the DARs pass compiler-side checks, but this is much less likely to indicate an issue because the DARs are typechecked during compilation.

```
> daml upgrade-check --compiler helper-1.0.0.dar dep-1.0.0.dar main-1.0.0.dar dep-
↪2.0.0.dar main-2.0.0.dar
...
```

14.3.6.2 Dry Run Uploading to a Test Environment

If you have a test environment with DARs that are not available to you, you may not be able to supply a complete list of DARs for your previous model to the standalone `upgrade-check` tool.

In this case, we recommend that as a further check for the validity of your upgraded package, you perform a dry-run upload of your package to a testing environment, using the `--dry-run` flag of the `daml ledger upload-dar` command. This also runs the upgrade typechecking, but does not persist your package to the ledger.

For workflows involving multiple DARs, we recommend more robust testing by running a Canton sandbox with the same version and environment as your in-production participant and uploading all the old and new packages that constitute your Daml app.

14.3.6.3 Daml Script Testing

Daml Script has been used for demonstrative purposes in this document, however usually the complexities of live upgrades comes with your workflows, not the data transformations themselves. You can use Daml Script (with Canton) to test some isolated simple cases, but for thorough tests of you system using SCU, you should prefer full [Workflow Testing](#).

We recommend placing your Daml Script tests in a separate package which depends on all versions of your business logic when testing your upgrades with Daml Script. This testing package should not be uploaded to the ledger if possible, as it depends on the `daml-script-lts` package. This package emits a warning on the participant when uploaded, as it serves no purpose on a participant, cannot be fully removed (as with any package), and may not be uploadable to the ledger in future versions (Daml 3). More information about this limitation [here](#).

Depending on multiple versions of the same package does however face ambiguity issues with imports. You can resolve these issues using [module prefixes](#):

```
name: my-testing-package
...
data-dependencies:
  - my/v1/main-package.dar
  - my/v2/main-package.dar
module-prefixes:
  main-1.0.0.dar: V11
  main-1.1.0.dar: V12
```

It is important to verify old workflows are still functional under new data and new implementation when writing your tests. You also need to verify that any new workflows intended to be backward compatible can consume old data. You should build your testing structure to cover this how you see fit, but we give the following recommendation as a starting point:

If your new version only includes choice body or interface instance changes (that is, it is a patch release)

Run your existing test suite for V1 but updated to call V2 choices. This can be done with a rewrite, or by passing down a [package preference](#) and calling the test with both the V1 and V2 package ID.

If your new version includes data changes, be that to contract payloads or choices (that is, it is a minor release)

Assuming your data change affects a template payload, write separate setup code for V1 and V2, populating new fields

```
setupV1 : Script V1TestData
```

```
setupV2 : Script V2TestData
```

These new data types should mostly just hold Contract IDs

Update your existing test suite from V1 to take a [package preference](#), allowing the V2 implementation without additional fields to choices to be called.

```
testV1 : [PackageId] -> V1TestData -> Script ()
```

Run the above test suite against V1 data, passing a V1 preference, then a V2 preference.

This ensures your changes haven't broken any existing workflows.

Next write tests for your new/modified workflows, using the V2 choice implementations. This does not need a package preference.

```
testV2 : V2TestData -> Script ()
```

Run these tests against both the V1 setup and the V2 setup, to ensure your new workflows support existing/old templates.

In order to do this, you'll need some way to upcast your `V1TestData`, i.e.

```
upcastTestData : V1TestData -> V2TestData
```

This function should mostly just call `coerceContractId` on any contract IDs, and fill in any `None` values if needed.

Finally, you can cover any workflows that require the contract data to already be upgraded (new fields populated), these are written entirely in V2 without any special considerations.

14.3.6.4 Multi-package builds for upgrades

When you are developing upgrades, you may have multiple DARs in scope that need to be built together. Tracking these DARs and building them in the right order can be complicated, especially as you develop live and as the project grows.

[Multi-package builds](#) help with projects containing multiple DARs, for example, a project using upgrades.

To understand how multi-package builds simplify the development of a project using upgrades, begin by creating a new Daml project with the `upgrades-example` template.

```
> daml new upgraded-iou --template upgrades-example
> cd upgraded-iou
> tree
.
├── multi-package.yaml
├── run-test.sh
├── interfaces
│   ├── daml/...
│   └── daml.yaml
├── main-v1
│   ├── daml/...
│   └── daml.yaml
├── main-v2
│   ├── daml/...
│   └── daml.yaml
└── test
    ├── daml/...
    └── daml.yaml
```

The example template contains:

A package `upgraded-iou-interfaces`, which defines an interface `Asset` and a viewtype `Asset.View`.

The first version (1.0.0) of a package `upgraded-iou-main`, which defines a template `IOU` with instance of `upgraded-iou-interfaces:Main.Asset`.

The second version (2.0.0) of `upgraded-iou-main` which upgrades the first. It adds a new `description` field to `IOU`, and uses it (when the field is defined) in an upgraded implementation of `Asset`.

A testing package `upgraded-iou-test`, which depends on both `upgraded-iou-main-1.0.0` and `upgraded-iou-main-2.0.0`. It defines a script which exercises `v1.0.0` and `v2.0.0` `IOU`'s via their `Asset` interface.

A script `run-test.sh`, which runs the main test in `upgraded-iou-test`.

A `multi-package.yaml` file which lists our four packages.

Without multi-package builds you would test your program like this:

```
> # Run sandbox in the background, wait until the three lines below are shown
> daml sandbox &
Starting Canton sandbox.
Listening at port 6865
Canton sandbox is ready.
> # Build all, run test
> cd interfaces/; daml build --enable-multi-package=no
> cd ../main-v1/; daml build --enable-multi-package=no
> cd ../main-v2/; daml build --enable-multi-package=no
> cd ../test/; daml build --enable-multi-package=no
> cd ..
> ./run-test.sh
> # Modify v2, run test
> cd main-v2/
> ... modify main-v2 ...
> daml build --enable-multi-package=no
> cd ../test/; daml build --enable-multi-package=no
> cd ..
> # Modify test, run test
> cd test/
> daml build --enable-multi-package=no
> cd ..
> ./run-test.sh
...
Test output:
...
> kill %1 # Kill backgrounded sandbox process
```

Forgetting to rebuild packages after changing their source would not cause a failure - for example, if you modified the source from `main-v2` in an incompatible way but did not recompile it, the `test` package would still compile successfully against the previous DAR for `main-v2`.

```
> # Modify main-v2 in an incompatible way
> cd main-v2/
> ... add a non-optional field `currency: Text` to template T in main-v2 ...
> cd ../test/
> daml build --enable-multi-package=no
...
Created .daml/dist/upgraded-iou-upgrades-template-test-1.0.0.dar
> # Compiling `test` succeeded even though main-v2 was changed incorrectly
```

With Daml multi-package builds, all builds automatically rebuild dependencies if their source has changed:

```
> cd test/
> daml build # --enable-multi-package is set to true by default
...
Building /home/dylanthinnes/ex-upgrades-template/main-v2
...
Severity: DsError
Message:
error type checking template Main.IOU :
  The upgraded template IOU has added new fields, but the following new fields
  are not Optional:
    Field 'currency' with type Text
```

(continues on next page)

(continued from previous page)

```
...
> # Compiling `test` failed as expected because main-v2 was changed incorrectly
```

The `./run-test.sh` script automatically rebuilds all DARs in the package that need to be rebuilt:

```
> daml sandbox & # Start sandbox in background
Starting Canton sandbox.
Listening at port 6865
Canton sandbox is ready.
> ... Fix main-v2 by dropping non-optional `currency` field ...
> # Re-run test
> ./run-test.sh
...
Building /home/dylanthinnes/ex-upgrades-template/main-v2
...
> # Modify test, run test
> ... modify test ...
> daml build --all
> ./run-test.sh
```

Multi-package builds invoked by `daml build --all` always recompile stale dependencies and DARs in order. This ensures a fully up-to-date package environment before running `./run-test.sh`.

14.3.6.5 Workflow Testing

While testing your workflows is application-specific, we still recommend at least one test for your core workflows that follows this pattern:

1. Start your app using version 2.0 of your DAR, but only upload version 1.0.
2. Initialize the app and start one instance of every core workflow.
3. Upload version 2.0 of your DAR.
4. Switch your backends to start using version 2.0, ideally this should be a flag.
5. Validate that the core workflows are in the same state and advance them to check that they are not stuck.

14.3.7 SCU Support in Daml Tooling

14.3.7.1 Codegen

For packages that support SCU (i.e. LF1.17), generated code uses package names in place of package IDs in template IDs. Retrieved data from the ledger is subject to the upgrade transformations described in previous sections.

Concretely, this is implemented as follows:

Java

The classes that are generated for each template and interface contain a `TEMPLATE_ID` field, which, for upgradable packages, now use a package name rather than a package ID. To help you determine the package ID of these packages, we have added a new `PACKAGE_ID` field to all such classes. Upgradable packages also have `PACKAGE_NAME` and `PACKAGE_VERSION` fields.

If you need to identify a template by the specific package ID of the DAR from which the code was generated, you can use the `TEMPLATE_ID_WITH_PACKAGE_ID` field, which is on all generated classes and their companion objects. When submitting commands you may also use the `packageIdSelectionPreference` to explicitly specify which package ID(s) you want the ledger to use to interpret the commands. Note that using these options prevents your application from seamlessly supporting upgrades.

TypeScript

The `templateId` field on generated template classes has been updated to use the package name as the package qualifier for upgrade-compatible packages. This is used for command submission and queries. However, note that queries return the package qualifier with the package ID rather than the package name. Generated modules now also give the `package` reference, which is the package name for upgrade-compatible packages; for other packages it is the package ID.

To perform package ID-qualified commands/queries in an upgrade compatible package, create a copy of the template object using the following:

```
const MyTemplateWithPackageId = {
  ...pkg.Mod.MyTemplate,
  templateId: `${pkg.packageId}:Mod:MyTemplate`,
}
```

14.3.7.2 JSON API Server

Template IDs may still be used with a package ID; however, for packages built as LF 1.17 or greater, the package may also be identified by name. That is to say, for upgradable packages a template ID can have the form `#<package-name>:<module-name>:<template-name>`, and this is resolved to corresponding templates from all packages which share this name and are built at 1.17 or above. For packages built at LF 1.15, the templates are not identifiable via a package name, and a package ID must be used.

Note: template IDs in query results always use a package ID. This allows you to distinguish the source of a particular contract. This means that if you use a template with a package name in the request, you can no longer expect the template IDs in the result to exactly match the input template ID.

Package ID selection preference: preferences apply to JSON API where you can specify your preferred selection of package versions.

14.3.7.3 PQS

To match the package-name changes to the Ledger API, PQS has changed how packages are selected for queries. All queries that take a Daml identity in the form `<package-id>:<module-name>:<template-name>` now take a package name in place of package ID. Note that this differs from the Ledger API in that the `#` prefix is not required for PQS, as PQS has dropped direct package ID queries. Queries for package names return all versions of a given contract, alongside the package version and package ID for each contract.

Note: If you still need to perform a query with an explicit package ID, you can either use a previous version of PQS or add the following filter predicate to your query: `SELECT * FROM active('my_package:My.App:MyTemplate') WHERE package_id = 'my_package_id'`

Given that PQS uses a document-oriented model for ledger content (JSONB), extensions to contract payloads are handled simply by returning the additional data in the blob.

14.3.7.4 Daml Shell

Daml Shell builds on PQS by providing a shell interface to inspect the ledger using package name to create an integrated view of all versions of contracts.

14.3.7.5 Daml-Script

Daml 2.10 introduces a new version of Daml Script which can be used by depending on `daml-script-lts` in your `daml.yaml`, as described in *Writing your first upgrade*. This version of Daml Script supports upgrades over the Ledger API.

All commands and queries in this version of Daml Script now use upgrades/downgrades automatically to ensure that they exercise the correct versions of choices and return correct payloads.

The following additional functionality is available for more advanced uses of SCU.

Exact commands

Each of the four submission commands now has an `exact` variant: `createExactCmd`, `exerciseExactCmd`, `exerciseByKeyExactCmd`, and `createAndExerciseExactCmd`. These commands force the participant to use the exact version of the package that your script uses, so you can be certain of the choice code you are calling. Note that exact and non-exact commands can be mixed in the same submission.

Daml Script Package Preference

A submission can specify a [package preference](#) as a list of package IDs:

```
(actAs alice <> packagePreference [myPackageId]) `submitWithOptions` createCmd ...
```

Note the use of `submitWithOptions` : `SubmitOptions -> Commands a -> Script a`. You can build `SubmitOptions` by combining the `actAs` and `packagePreference` functions with `<>`.

The full list of builders for `SubmitOptions` is as follows:

```
-- `p` can be `Party`, `[Party]`, etc.
actAs : IsParties p => p -> SubmitOptions
readAs : IsParties p => p -> SubmitOptions

disclose : Disclosure -> SubmitOptions
discloseMany : [Disclosure] -> SubmitOptions

newtype PackageId = PackageId Text
packagePreference : [PackageId] -> SubmitOptions
```

A `PackageId` can be hard-coded in your script, in which case it must be updated whenever the package changes. Otherwise, it can be provided using the `--input-file` flag of the `daml script` command line tool.

The following example demonstrates reading the package ID from a DAR and passing it to a script:

```
# Path to the dar you want to pass as package preference.
PACKAGE_DAR=path/to/main/dar.dar
# Path to the dar containing the Daml script for which you want to pass the
↳package-id
SCRIPT_DAR=path/to/script/dar.dar
# Extract the package-id of PACKAGE_DAR's main package.
daml damlc inspect-dar ${PACKAGE_DAR} --json | jq '.main_package_id' > ./package-
↳id-script-input.json
# replace --ide-ledger with --ledger-host and --ledger-port for deployed Canton
daml script --dar ${SCRIPT_DAR} --script-name Main:main --ide-ledger --input-file
↳./package-id-script-input.json
```

Following this, your script would look like:

```
module Main where

import Daml.Script

main : Text -> Script ()
main rawPkgId = do
  let pkgId = PackageId rawPkgId
  alice <- allocateParty "alice"
  -- Commands omitted for brevity
  let submitOptions = actAs alice <> packagePreference [pkgId]
  submitOptions `submitWithOptions` createCmd ...
```

14.3.7.6 Daml Studio support

Daml Studio runs a reference model of Canton called the IDE Ledger. This ledger has been updated to support the relevant parts of the Smart Contract Upgrades feature.

14.4 Automating the Upgrade Process

In this section, we are going to automate the upgrade of our carbon certificate process using [Daml Script](#) and Daml Triggers ([deprecated](#)). Note that automation for upgrades is specific to an individual application, just like the upgrade models. Nevertheless, we have found that the pattern shown here occurs frequently.

This section describes manual upgrading steps when deploying updated Daml application code, by migrating contracts from one version to another. A production-grade, optimized migration tool that automates this application upgrade process is available, but it requires a Daml Enterprise license. Its PDF manual explains how a Daml developer implements a smart contract upgrade migration. The manual also advises an operations team on how to perform the contract migration.

The tool is designed to accommodate:

- Working with a stale view of the ledger's state (e.g., a partial migration was recently performed);
- Reduce effort by boilerplate code generation for unchanged templates;
- It has idempotent operations where possible;
- Very large ACS sizes; and
- Robustly handles rejected ledger commands (e.g., archiving a contract in the same Daml transaction that creates an upgraded replacement helps to ensure that duplicate replacement contracts are not created).

Please contact your account manager or [DA support](#) for access to the upgrade tool.

14.4.1 Structure the Upgrade

There are three kinds of actions performed during the upgrade:

1. Alice creates `UpgradeCarbonCertProposal` contracts. We assume here, that Alice wants to upgrade all `CarbonCert` contracts she has issued. Since the `UpgradeCarbonCertProposal` proposal is specific to each owner, Alice has to create one `UpgradeCarbonCertProposal` per owner. There can be potentially many owners but this step only has to be performed once assuming Alice will not issue more `CarbonCert` contracts after this point.
2. Bob and other owners accept the `UpgradeCarbonCertProposal`. To keep this example simple, we assume that there are only carbon certificates issued by Alice. Therefore, each owner has to accept at most one proposal.
3. As owners accept upgrade proposals, Alice has to upgrade each certificate. This means that she has to execute the upgrade choice once for each certificate. Owners will not all accept the upgrade at the same time and some might never accept it. Therefore, this should be a long-running process that upgrades all carbon certificates of a given owner as soon as they accept the upgrade.

Given those constraints, we are going to use the following tools for the upgrade:

1. A Daml script that will be executed once by Alice and creates an `UpgradeCarbonCertProposal` contract for each owner.

2. Navigator to accept the `UpgradeCarbonCertProposal` as Bob. While we could also use a Daml script to accept the proposal, this step will often be exposed as part of a web UI so doing it interactively in Navigator resembles that workflow more closely.
3. A long-running Daml trigger that upgrades all `CarbonCert` contracts for which there is a corresponding `UpgradeCarbonCertAgreement`.

14.4.2 Implementation of the Daml Script

In our Daml Script, we are first going to query the ACS (Active Contract Set) to find all `CarbonCert` contracts issued by us. Next, we are going to extract the owner of each of those contracts and remove any duplicates coming from multiple certificates issued to the same owner. Finally, we iterate over the owners and create an `UpgradeCarbonCertAgreement` contract for each owner.

```
initiateUpgrade : Setup.Parties -> Script ()
initiateUpgrade Setup.Parties{alice} = do
  certs <- query @CarbonCert alice
  let myCerts = filter (\(_cid, c) -> c.issuer == alice) certs
  let owners = dedup $ map (\(_cid, c) -> c.owner) myCerts
  forA_ owners $ \owner -> do
    debugRaw ("Creating upgrade proposal for: " <> show owner)
    submit alice $ createCmd (UpgradeCarbonCertProposal alice owner)
```

14.4.3 Implementation of the Daml Trigger

Our trigger does not need any custom user state and no heartbeat so the only interesting field in its definition is the rule.

```
upgradeTrigger : Trigger ()
upgradeTrigger = Trigger with
  initialize = pure ()
  updateState = \_msg -> pure ()
  registeredTemplates = AllTemplates
  heartbeat = None
  rule = triggerRule
```

In our rule, we first filter out all agreements and certificates issued by us. Next, we iterate over all agreements. For each agreement we filter the certificates by the owner of the agreement and finally upgrade the certificate by exercising the `Upgrade` choice. We mark the certificate as pending which temporarily removes it from the ACS and therefore stops the trigger from trying to upgrade the same certificate multiple times if the rule is triggered in quick succession.

```
triggerRule : Party -> TriggerA () ()
triggerRule issuer = do
  agreements <-
    filter (\(_cid, agreement) -> agreement.issuer == issuer) <$>
    query @UpgradeCarbonCertAgreement
  allCerts <-
    filter (\(_cid, cert) -> cert.issuer == issuer) <$>
    query @CarbonCert
  forA_ agreements $ \ (agreementCid, agreement) -> do
    let certsForOwner = filter (\(_cid, cert) -> cert.owner == agreement.owner)
    ↪ allCerts
```

(continues on next page)

(continued from previous page)

```
forA_ certsForOwner $ \(certCid, _) ->
  emitCommands
    [exerciseCmd agreementCid (Upgrade certCid)]
    [toAnyContractId certCid]
```

The trigger is a long-running process and the rule will be executed whenever the state of the ledger changes. So whenever an owner accepts an upgrade proposal, the trigger will run the rule and upgrade all certificates of that owner.

14.4.4 Deploy and Execute the Upgrade

Now that we defined our Daml script and our trigger, it is time to use them! If you still have Sandbox running from the previous section, stop it to clear out all data before continuing.

First, we start sandbox passing in the carbon-upgrade DAR. Since a DAR includes all transitive dependencies, this includes carbon-1.0.0 and carbon-2.0.0.

```
$ cd example/carbon-upgrade
$ daml sandbox --dar .daml/dist/carbon-upgrade-1.0.0.dar
```

To simplify the setup here, we use a Daml script to create 3 parties Alice, Bob and Charlie and two CarbonCert contracts issues by Alice, one owned by Bob and one owned by Charlie. This Daml script reuses the Setup.setup Daml script from the previous section to create the parties & users.

```
setup : Script Setup.Parties
setup = do
  parties@Setup.Parties{..} <- Setup.setup
  bobProposal <- submit alice $ createCmd (CarbonCertProposal alice bob 10)
  submit bob $ exerciseCmd bobProposal CarbonCertProposal_Accept
  charlieProposal <- submit alice $ createCmd (CarbonCertProposal alice charlie 5)
  submit charlie $ exerciseCmd charlieProposal CarbonCertProposal_Accept
  pure parties
```

Run the script as follows:

```
$ cd example/carbon-initiate-upgrade
$ daml build
$ daml script --dar=.daml/dist/carbon-initiate-upgrade-1.0.0.dar --script-
↳ name=InitiateUpgrade:setup --ledger-host=localhost --ledger-port=6865 --output-
↳ file parties.json
```

As before, parties.json contains the actual party ids we can use later.

If you now start Navigator from the carbon-initiate-upgrade directory and log in as alice, you can see the two CarbonCert contracts.

Next, we run the trigger for Alice. The trigger will keep running throughout the rest of this example.

```
$ cd example/carbon-upgrade-trigger
$ daml build
$ daml trigger --dar=.daml/dist/carbon-upgrade-trigger-1.0.0.dar --trigger-
↳ name=UpgradeTrigger:upgradeTrigger --ledger-host=localhost --ledger-port=6865 --
↳ ledger-user=alice
```

With the trigger running, we can now run the script to create the `UpgradeCarbonCertProposal` contracts (we could also have done that before starting the trigger). The script takes an argument of type `Parties` corresponding to the result of the previous `setup` script. We can pass this in via the `--input-file` argument.

```
$ cd example/carbon-initiate-upgrade
$ daml build
$ daml script --dar=.daml/dist/carbon-initiate-upgrade-1.0.0.dar --script-
↪name=InitiateUpgrade:initiateUpgrade --ledger-host=localhost --ledger-port=6865
↪--input-file=parties.json
```

At this point, our trigger is running and the `UpgradeCarbonCertProposal` contracts for Bob and Charlie have been created. What is left to do is to accept the proposals. Our trigger will then automatically pick them up and upgrade the `CarbonCert` contracts.

First, start Navigator and log in as `bob`. Click on the `UpgradeCarbonCertProposal` and accept it. If you now go back to the contracts tab, you can see that the `CarbonCert` contract has been archived and instead there is a new `CarbonCertWithMethod` upgrade. Our trigger has successfully upgraded the `CarbonCert`!

Next, log in as `charlie` and accept the `UpgradeCarbonCertProposal`. Just like for Bob, you can see that the `CarbonCert` contract has been archived and instead there is a new `CarbonCertWithMethod` contract.

Since we upgraded all `CarbonCert` contracts issued by Alice, we can now stop the trigger and declare the update successful.

Chapter 15

Developer Tools

15.1 Daml Assistant

`daml` is a command-line tool that does a lot of useful things related to the SDK. Using `daml`, you can:

Create new Daml projects: `daml new <path to create project in>`

Create a new project based on the `create-daml-app` template: `daml new --template=create-daml-app <path to create project in>`

Initialize a Daml project: `daml init`

Compile a Daml project: `daml build`

This builds the Daml project according to the project config file `daml.yaml` (see [Configuration files](#) below).

In particular, it will download and install the specified version of the Daml SDK (the `sdk-version` field in `daml.yaml`) if missing, and use that SDK version to resolve dependencies and compile the Daml project.

Launch the tools in the SDK:

- Launch [Daml Studio](#): `daml studio`
- Launch [Sandbox](#), [Navigator](#) and the [HTTP JSON API Service](#): `daml start` You can disable the HTTP JSON API by passing `--json-api-port none` to `daml start`. To specify additional options for sandbox/navigator/the HTTP JSON API you can use `--sandbox-option=opt`, `--navigator-option=opt` and `--json-api-option=opt`.
- Launch Sandbox: `daml sandbox`
- Launch Navigator (Deprecated): `daml navigator`
- Launch the [HTTP JSON API Service](#): `daml json-api`
- Run [Daml codegen](#): `daml codegen`

Install new SDK versions manually: `daml install <version>`

Note that you need to update your *project config file* `<#configuration-files>` to use the new version.

15.1.1 Command Help

To see information about any command, run it with `--help`.

15.1.2 Configuration Files

The Daml assistant and the SDK are configured using two files:

- The global config file, one per installation, which controls some options regarding SDK installation and updates

- The project config file, one per Daml project, which controls how the SDK builds and interacts with the project

15.1.2.1 Global Config File (`daml-config.yaml`)

The global config file `daml-config.yaml` is in the `daml` home directory (`~/.daml` on Linux and Mac, `C:/Users/<user>/AppData/Roaming/daml` on Windows). It controls options related to SDK version installation and upgrades.

By default it's blank, and you usually won't need to edit it. It recognizes the following options:

- `auto-install`: whether `daml` automatically installs a missing SDK version when it is required (defaults to `true`)

- `update-check`: how often `daml` will check for new versions of the SDK, in seconds (default to 86400, i.e. once a day)

 - This setting is only used to inform you when an update is available.

 - Set `update-check`: `<number>` to check for new versions every N seconds. Set

 - `update-check`: `never` to never check for new versions.

- `artifactory-api-key`: If you have a license for Daml EE, you can use this to specify the Artifactory API key displayed in your user profile. The assistant will use this to download the EE edition.

Here is an example `daml-config.yaml`:

```
auto-install: true
update-check: 86400
```

15.1.2.2 Project Config File (`daml.yaml`)

The project config file `daml.yaml` must be in the root of your Daml project directory. It controls how the Daml project is built and how tools like Sandbox and Navigator interact with it.

The existence of a `daml.yaml` file is what tells `daml` that this directory contains a Daml project, and lets you use project-aware commands like `daml build` and `daml start`.

`daml init` creates a `daml.yaml` in an existing folder, so `daml` knows it's a project folder.

`daml new` creates a skeleton application in a new project folder, which includes a config file. For example, `daml new my_project` creates a new folder `my_project` with a project config file `daml.yaml` like this:

```

sdk-version: __VERSION__
name: __PROJECT_NAME__
source: daml
init-script: Main:setup
parties:
  - Alice
  - Bob
version: 1.0.0
exposed-modules:
  - Main
dependencies:
  - daml-prim
  - daml-stdlib
script-service:
  grpc-max-message-size: 134217728
  grpc-timeout: 60
  jvm-options: []
build-options: ["--ghc-option", "-Werror",
                  "--ghc-option", "-v"]

```

Here is what each field means:

sdk-version: the SDK version that this project uses.

The assistant automatically downloads and installs this version if needed (see the `auto-install` setting in the global config). We recommend keeping this up to date with the latest stable release of the SDK. It is possible to override the version without modifying the `daml.yaml` file by setting the `DAML_SDK_VERSION` environment variable. This is mainly useful when you are working with an external project that you want to build with a specific version.

The assistant will warn you when it is time to update this setting (see the `update-check` setting in the global config to control how often it checks, or to disable this check entirely).

name: the name of the project. This determines the filename of the `.dar` file compiled by `daml build`.

source: the root folder of your Daml source code files relative to the project root.

init-script: the name of the Daml script to run when using `daml start`.

parties: the parties to display in the Navigator when using `daml start`.

version: the project version.

exposed-modules: the Daml modules that are exposed by this project, which can be imported in other projects. If this field is not specified all modules in the project are exposed.

dependencies: library-dependencies of this project. See [Reference: Daml Packages](#).

data-dependencies: Cross-SDK dependencies of this project See [Reference: Daml Packages](#).

module-prefixes: Prefixes for all modules in package See [Reference: Daml Packages](#).

script-service: settings for the script service

- **grpc-max-message-size:** This option controls the maximum size of gRPC messages. If unspecified this defaults to 128MB (134217728 bytes). Unless you get errors, there should be no reason to modify this.
- **grpc-timeout:** This option controls the timeout used for communicating with the script service. If unspecified this defaults to 60s. Unless you get errors, there should be no reason to modify this.
- **jvm-options:** A list of options passed to the JVM when starting the script service. This can be used to limit maximum heap size via the `-Xmx` flag.

build-options: a list of tokens that will be appended to some invocations of `damlc` (currently

build and *ide*). Note that there is no further shell parsing applied.

`sandbox-options`: a list of options that will be passed to Sandbox in `daml start`.

`navigator-options`: a list of options that will be passed to Navigator in `daml start`.

`json-api-options`: a list of options that will be passed to the HTTP JSON API in `daml start`.

`script-options`: a list of options that will be passed to the Daml script runner when running the `init-script` as part of `daml start`.

`start-navigator`: Controls whether navigator is started as part of `daml start`. Defaults to `true`. If this is specified as a CLI argument, say `daml start --start-navigator=true`, the CLI argument takes precedence over the value in `daml.yaml`.

The `daml.yaml` file supports [Environment Variable Interpolation](#).

15.1.2.3 Recommended `build-options`

The default set of warnings enabled by the Daml compiler is fairly conservative. When you are just starting out, seeing a huge set of warnings can easily be overwhelming and distract from what you are actually working on. However, as you get more experienced and more people work on a Daml project, enabling additional warnings (and enforcing their absence in CI) can be useful.

Here are `build-options` you might declare in a project's `daml.yaml` for a stricter set of warnings.

```
build-options:
- --ghc-option=-Wunused-top-binds
- --ghc-option=-Wunused-matches
- --ghc-option=-Wunused-do-bind
- --ghc-option=-Wincomplete-uni-patterns
- --ghc-option=-Wredundant-constraints
- --ghc-option=-Wmissing-signatures
- --ghc-option=-Werror
```

Each option enables a particular warning, except for the last one, `-Werror`, which turns every warning into an error; this is especially useful for CI build arrangements. Simply remove or comment out any line to disable that category of warning. See [the Daml forum](#) for a discussion of the meaning of these warnings and pointers to other available warnings.

15.1.2.4 Multi-Package Config File (`multi-package.yaml`)

See [Multi-Package Build](#) for more information on this file. The `multi-package.yaml` file is used to inform Daml Build and the IDE of projects containing multiple connected Daml packages.

An example is given below:

```
packages:
- ./path/to/package/a
- ./path/to/package/b
projects:
- ./path/to/project/a
- ./path/to/project/b
```

Here is what each field means:

`packages`: an optional list of directories containing Daml packages, and by extension, `daml.yaml` config files. These allow Daml Multi-Build to find the source code for dependency DARs and build them in topological order.

`projects`: an optional list of directories containing `multi-package.yaml` config files, which will extend the above package set for resolving the build order. These exist to allow separation of your project into sub-projects which can still be built when removed from the surrounding environment.

The `multi-package.yaml` file supports [Environment Variable Interpolation](#).

15.1.2.5 Environment Variable Interpolation

Both the `daml.yaml` and `multi-package.yaml` config files support environment variable interpolation on all string fields. Interpolation takes the form of `${MY_ENVIRONMENT_VARIABLE}`, which is replaced with the content of `MY_ENVIRONMENT_VARIABLE` from the calling shell. These can be escaped and placed within strings according to the environment variable interpolation semantics.

This allows you to extract common data, such as the `sdk-version`, `package-name`, or `package-version` outside of a package's `daml.yaml`. For example, you can use an `.envrc` file or have these values provided by a build system. This feature can also be used for specifying dependency DARs, enabling you to either store your DARs in a common folder and pass its directory as a variable, shortening the paths in your `daml.yaml`, or pass each dependency as a separate variable through an external build system, which may store them in a temporary cache.

The following example showcases this:

```

sdk-version: ${SDK_VERSION}
name: ${PROJECT_NAME}_test
source: daml
version: ${PROJECT_VERSION}
dependencies:
  // Using a common directory
  ${DEPENDENCY_DIRECTORY}/my-dependency-1.0.0.dar
  ${DEPENDENCY_DIRECTORY}/my-other-dependency-1.0.0.dar
  // Passed directly by a build system
  ${DAML_FINANCE_DAR}
  ${MY_DEPENDENCY_DAR}

```

Escape syntax uses the `\` prefix: `\${NOT_INTERPOLATED}`, and interpolation can be disallowed for a config file by setting the `environment-variable-interpolation` field to `false`.

```

name: \${NOT_INTERPOLATED}
environment-variable-interpolation: false

```

Note that environment variables are case sensitive, meaning `${MY_VAR}` and `${My_Var}` do not reference the same variable.

15.1.3 Managing SDK Versions

You can manage SDK versions manually by using `daml install`.

To download and install the SDK of the latest stable Daml version:

```
daml install latest
```

To download and install the latest snapshot release:

```
daml install latest --snapshots=yes
```

Please note that snapshot releases are not intended for production usage.

To install the SDK version specified in the project config, run:

```
daml install project
```

To install a specific SDK version, for example version 2.0.0, run:

```
daml install 2.0.0
```

Rarely, you might need to install an SDK release from a downloaded SDK release tarball. **This is an advanced feature:** you should only ever perform this on an SDK release tarball that is released through the official `digital-asset/daml` github repository. Otherwise your `daml` installation may become inconsistent with everyone else's. To do this, run:

```
daml install path-to-tarball.tar.gz
```

By default, `daml install` will update the assistant if the version being installed is newer. You can force the assistant to be updated with `--install-assistant=yes` and prevent the assistant from being updated with `--install-assistant=no`.

See `daml install --help` for a full list of options.

15.1.4 Build Daml Projects

15.1.4.1 Build a project

To compile your Daml source code into a Daml archive (a `.dar` file), run:

```
daml build
```

You can control the build by changing your project's `daml.yaml`:

name The name of the project.

version The project version.

source The path to the source code.

By default, the generated `.dar` file is created in `.daml/dist/${name}-${version}.dar`. To override the default location, pass the `-o` argument to `daml build`:

```
daml build -o path/to/darfile.dar
```

15.1.4.2 Build multiple packages

`daml build` supports multi-package builds, an optional feature for building and managing multiple interdependent packages simultaneously. The multi-package build feature consists of a configuration file and a set of flags.

You can use multi-package builds to:

- Configure `daml build` to automatically rebuild DARs used in data dependencies, when the source code corresponding to those DARs changes
- Build all of the packages in a project simultaneously, using `daml build --all`
- Clean all build artifacts in a project, using `daml clean --all`

Daml Studio also supports multi-package projects, which is covered [here](#).

Overview

To use multi-package builds, create a `multi-package.yaml` configuration file at the root of the project. This file serves as a register of the interdependent packages in your project.

`multi-package.yaml`

```
packages:
- <path to first package>
- <path to second package>
```

Once `multi-package.yaml` is in place, you can run `daml build --all` to build all the packages listed in the `multi-package.yaml` file. Or you can run `daml build` within a package to build that package and its dependencies.

If you don't want to use multi-package builds, omit the `multi-package.yaml` file from your project.

Note: `multi-package.yaml` assumes that dependent packages use the default `daml build` locations for DAR files. If you have shell scripts that move a package's DAR file after building, you'll need to use the [output flag](#) instead.

Build without multi-package

As context for the multi-package illustrations in later sections, here's an example of how to use `daml build` without the multi-package feature:

```
> # ... make changes to Model ...
> cd ../package-Model/ # Navigate to package-Model
> daml build           # Build Model.dar
> cd ../package-Logic/ # Navigate to package-Logic
> daml build           # Build Logic.dar
```

Multi-package configuration

To configure which packages to build automatically, list the packages under a `packages:` header in your `multi-package.yaml` configuration file:

`multi-package.yaml`

```
packages:
- <path to package>
- <path to package>
```

For each package, specify the relative path to the directory containing the `daml.yaml` file for that package.

Example

In this example, the Daml project contains two packages, `package-Model` and `package-Logic`. The `multi-package.yaml` file at the root of the project contains relative paths to the Model and Logic packages.

`multi-package.yaml`

```
packages:
- ./package-Logic
- ./package-Model
```

Here's the resulting project tree:

```
> tree
.
├── multi-package.yaml
├── package-Logic
│   ├── daml/...
│   └── daml.yaml
└── package-Model
    ├── .daml/dist/package-Model-1.0.0.dar
    ├── daml/...
    └── daml.yaml
```

With this configuration, running `daml build` on `package-Logic` also automatically rebuilds `package-Model-1.0.0.dar` as a data dependency of `package-Logic`.

```
> # ... make changes to Model ...
> cd ./package-Logic/ # Navigate to package-Logic
> daml build # Build package Logic
...
Dependency "package-Model" is stale, rebuilding...
...
Building "package-Logic"...
Done.
```

With multi-package builds configured, you can run `daml build` just once to build interdependent packages, with a guarantee that changes to dependencies are always propagated wherever they are needed.

Build all packages in a project

To build all packages in a project, use the `--all` flag. This flag builds every package listed in the specified `multi-package.yaml`. With the `--all` flag, you can run `daml build` from outside a package directory.

How the CLI finds `multi-package.yaml`

In most cases, you'll run `daml build` and `daml clean` from deeper in your project structure than the root. The discovery logic for these commands follows the patterns of `daml.yaml`:

1. If a path is specified with `--multi-package-path PATH`, use the `multi-package.yaml` at that location. (This is the `multi-package` equivalent to `--project-root`.)
2. Otherwise, search up the directory tree starting from the directory where either `daml build` or `daml clean` was invoked. Return the first `multi-package.yaml` encountered.
3. If no `multi-package.yaml` file is found in the preceding steps, do not use the multi-build feature.

Add a package to a multi-package configuration

In the example above, the `multi-package.yaml` file registers two packages, `Logic` and `Model`:

```
> tree
.
├── multi-package.yaml
├── package-Logic
│   ├── .daml/dist/package-Logic-1.0.0.dar
│   ├── daml/...
│   └── daml.yaml
└── package-Model
    ├── daml/.dist/package-Model-1.0.0.dar
    ├── daml/...
    └── daml.yaml
```

To add a new package called `Tests` to this example structure, run `daml new --template=empty-skeleton package-Tests`. This command creates an empty package named `package-Tests`, parallel to the existing `package-Logic` and `package-Model` packages.

```
> tree
.
├── multi-package.yaml
├── package-Logic
├── package-Model
└── package-Tests
```

In the newly created `package-Tests/daml.yaml`, remove the `sandbox-options` and add a dependency on the DAR for `Logic`:

```
data-dependencies:
- ../package-Logic/.daml/dist/package-Logic-1.0.0.dar
```

Finally, add `package-Testing` to the `multi-package.yaml` file:

multi-package.yaml

```
packages:
- ./package-Logic
- ./package-Model
+ - ./package-Tests
```

Run multi-package tests

There are two ways to build the new Tests package in this example:

Run `daml build` from the `package-Testing` directory to build the Tests package and its dependency package, Logic.

Run `daml build --all` from the root of the project to build all three packages in the project, including the Tests package.

After building the Tests package, you can run `daml test` from the `package-Testing` directory to run up-to-date tests.

Packages not listed in multi-package.yaml

Packages that are not included in the `multi-package.yaml` file are not automatically recompiled, even if their source is available in the project's source tree.

For example, a project's source tree might include a vendor library that should be built in isolation, even though the `vendor-library.dar` is a data dependency of `package-Logic`.

```
> tree
.
├── multi-package.yaml
├── package-Logic
│   ├── daml/...
│   └── daml.yaml
├── package-Model
│   ├── daml/...
│   ├── daml/.dist/package-Model-1.0.0.dar
│   └── daml.yaml
└── vendor-library
    ├── daml/...
    ├── daml/.dist/vendor-library-1.0.0.dar
    └── daml.yaml
```

As long as `vendor-library` is not included in `multi-package.yaml`, builds of `package Logic` will **not** automatically rebuild `vendor-library.dar`, even though its source and `vendor-library/daml.yaml` are available to the project. In other words, the `multi-package.yaml` configuration - not the project directory structure - controls the multi-package build feature.

```
> # ... make changes to vendor-library ...
> cd ./package-Logic/ # Navigate to package-Logic
> daml build # Build package Logic
...
Building "package-Logic"... # vendor-library is not rebuilt
Done.
```

In this way, `multi-package.yaml` provides a way to exclude packages and avoid recompiling a vendor package or other package outside the project owner's control.

Multiple `multi-package.yaml` files

Some projects use a nested structure. For example, you might have two separate GitHub repositories, `application` and `library`, in which you regularly change the source. The application repository depends on the library repository via `daml.yaml`, which points at DAR files within the library repository.

```

.
├── application-repository
│   ├── .git
│   ├── multi-package.yaml
│   ├── application-logic
│   │   └── daml.yaml
│   └── application-tests
│       └── daml.yaml
└── library-repository
    ├── .git
    ├── multi-package.yaml
    ├── library-logic
    │   └── daml.yaml
    └── library-tests
        └── daml.yaml

```

`application-repository/application-logic/daml.yaml`

```

version: 1.0.0
...
data-dependencies:
- ../../library-respository/library-logic/.daml/dist/library-logic-1.0.0.daml

```

Each repository has its own `multi-package.yaml` that points to the respective logic and tests packages, so that you can work effectively in each repository on its own.

```

> cd library-repository
> daml build --all
...
Building "library-logic"...
Building "library-tests"...
Done.
> cd application-repository
> daml build --all
...
Building "application-logic"...
Building "application-tests"...
Done.

```

But occasionally you might want to make changes to both repositories simultaneously. In this example, neither repository is aware of the other, so builds run from within the application repository will not rebuild dependencies within the library repository.

```
> cd library-repository
> editor library-logic/... # make some changes
> cd ../application-repository
> daml build --all
Nothing to do. # changes from library-logic are not picked up and not rebuilt
```

In cases like this, you can use the `projects` field of `multi-package.yaml` to include external `multi-package.yaml` files in the build.

`application-repository/multi-package.yaml`

```
packages:
- ./application-logic
- ./application-tests
# Add the path to library-repository, which includes a multi-package.yaml file
projects:
- ../library-repository
```

With this configuration, all dependencies in the external `multi-package.yaml` are included in `multi-package` builds local to the project.

```
> cd library-repository
> editor library-logic/... # make changes
> cd ../application-repository
> daml build --all
Building "library-logic"... # changes from library-logic *are* picked up and
↳ rebuilt
Building "application-logic" # application-logic is rebuilt because its library-
↳ logic dependency has changed
```

With the `projects:` field, a project can be composed of many `multi-package.yaml` files. Make sure your build command refers to the right `multi-package.yaml` for your use case.

Nested projects

The following example explores a nested project structure. The top-level main package has a `multi-package.yaml` file and a `libs` subdirectory. The `libs` subdirectory has its own `libs/multi-package.yaml` file and contains two packages, `libs/my-lib` and `libs/my-lib-helper`.

The main package depends on `my-lib`, which itself depends on `my-lib-helper`:

```
> tree
.
├── multi-package.yaml
├── libs
│   ├── multi-package.yaml
│   ├── my-lib
│   │   ├── daml
│   │   │   └── MyLib.daml
│   │   └── daml.yaml
│   └── my-lib-helper
│       ├── daml
│       │   └── MyLibHelper.daml
│       └── daml.yaml
```

(continues on next page)

(continued from previous page)

```

└─ main
   └─ daml
      └─ Main.daml
      └─ daml.yaml

```

Here are the key files:

libs/multi-package.yaml

```

packages:
- ./my-lib
- ./my-lib-helper

```

multi-package.yaml

```

packages:
- ./main
projects:
- ./libs

```

main/daml.yaml

```

version: 1.0.0
...
data-dependencies:
- ../libs/my-lib/.daml/dist/my-lib-1.0.0.dar # main depends on my-lib

```

Running `daml build --all` from the root of the project builds all libraries and main:

```

> # From the root of the project:
> daml build --all
Building "my-lib-helper"...
Building "my-lib"...
Building "main"...

```

But in this example, if you run `daml build --all` from the `libs` directory, the CLI traverses the directory tree and encounters `libs/multi-package.yaml` first. Because `libs/multi-package.yaml` only refers to `my-lib` and `my-lib-helper`, only those packages are built.

```

> cd libs/
> daml build --all
Building "my-lib-helper"...
Building "my-lib"...
# Main is *not* built, because libs/multi-package.yaml was used

```

To use the outer `multi-package.yaml` from within `libs`, add the `--multi-package-path` flag:

```

> cd libs/
> daml build --all --multi-package-path ../multi-package.yaml
Building "my-lib-helper"...
Building "my-lib"...
Building "main"... # Main *is* built, because the root multi-package.yaml was used

```

The `--output` flag

The `daml build` command has an optional `--output` flag, which sets the location of the generated DAR file. In multi-package builds, the `--output` flag applies if specified in the relevant package's `daml.yaml` build-options:

```
build-options:  
- --output=./my-dar.dar
```

Caching

Multi-package builds can include many packages and a whole project. For efficiency, the `daml build` command caches package results and avoids rebuilds when possible. `daml build` performs two checks on generated artifacts to ensure they are up-to-date:

- Compare the contents of all Daml source files against those compiled into the DAR.
- Compare the package IDs of all dependencies against the package IDs of dependencies compiled into the DAR.

To turn off caching for a build, use `--no-cache`. This flag forces rebuilding of all relevant packages.

Clean the cache

To clear out project build artifacts you no longer need, use `daml clean`:

- `daml clean` clears artifacts for the current package and its dependencies
- `daml-clean --all` clears artifacts for the entire project

When a multi-package `.yaml` file is in place, the `--all` flag clears the build artifacts of all packages in the project.

Multi-Package Builds and Upgrades

Multi-package builds can make testing and developing upgrades much easier. For more on this, consult the the documentation for [multi-package builds in upgrades](#).

15.1.5 Run Assistant Commands

15.1.5.1 Terminal command completion

The `daml` assistant comes with support for `bash` and `zsh` completions. These are installed automatically on Linux and Mac when you install or upgrade the Daml assistant.

If you use the `bash` shell, and your `bash` supports completions, you can use the TAB key to complete many `daml` commands, such as `daml install` and `daml version`.

For `Zsh` you first need to add `~/.daml/zsh` to your `$fpath`, e.g., by adding the following to the beginning of your `~/.zshrc` before you call `compinit`: `fpath=(~/.daml/zsh $fpath)`

You can override whether `bash` completions are installed for `daml` by passing `--bash-completions=yes` or `--bash-completions=no` to `daml install`.

15.1.5.2 Run commands outside of the project directory

In some cases, it can be convenient to run a command in a project without changing directories. For that use case, you can set the `DAML_PROJECT` environment variable to the path to the project:

```
DAML_PROJECT=/path/to/my/project daml build
```

Note that while some commands, most notably, `daml build`, accept a `--project-root` option, it can end up choosing the wrong SDK version so you should prefer the environment variable instead.

Important: [Daml Enterprise license](#) required

15.2 Daml Shell (`daml-shell`)

Daml Shell is a terminal-based application that enables you to inspect a Daml ledger by connecting to a live PQS datastore. With Daml Shell, you can examine current or historical states of the ledger by querying ledger events, transactions, and contracts. The Daml Shell CLI includes extensive help via the `help` command.

Some of the actions that Daml Shell supports are:

- Find a specific contract and display it. For example, if you have a contract ID, you can use Daml Shell to inspect the corresponding contract using the `contract` command.
- Find all events related to a transaction ID. A transaction is displayed as a series of ledger events (creates, archives, and exercises).
- Auto-completion for identifiers such as contract IDs, fully qualified names, and package names.
- List active, inactive, or all contracts for a template using a template FQN.
- Apply queries and filters to commands to manage the output.
- Use the `compare-contracts` command to highlight the delta between two contract IDs for the same template.

To bound a search, specify a minimum and maximum offset value.

Daml Shell leverages PQS as its datastore and connects using JDBC. For more information, see [Configuration](#)

15.2.1 Getting started

15.2.1.1 Prerequisites

Daml Shell connects to the PostgreSQL database of a Participant Query Store (PQS). For setup instructions, see the [PQS documentation](#).

15.2.1.2 Running Daml Shell

You can run Daml Shell from a `jar` artifact or from a Docker image ([tag list](#)).

```
docker run -it --net host digitalasset-docker.jfrog.io/daml-shell:<version-tag> #  
↪ version-tag format: x.y.z
```

15.2.1.3 Commands

The easiest way to discover commands and filters is to type the `help` command while Daml Shell is running.

You can recurse into commands by typing `help <command> <sub-command> [...]`. Auto-completion at the bottom of the screen suggests possible command options.

```
> help  
NAME
```

(continues on next page)

(continued from previous page)

`help - Display usage instructions`**SYNOPSIS**`help [<command>]`**DESCRIPTION**`CLI to interact with a PQS database.`**Available commands:**

- * `active` - active contracts
- * `archives` - archived contracts
- * `compare-contracts` - compare two contracts
- * `connect` - connect to JDBC URL
- * `contract` - contract by ID
- * `creates` - created contracts
- * `disconnect` - close database connection
- * `exercise` - choice by event-`id`
- * `exercises` - exercised choices
- * `go` - upper offset bound
- * `help` - Display usage instructions
- * `net-changes` - net contract counts
- * `quit` - quit the shell
- * `set` - configure application settings
- * `transaction` - transaction details

Available filters:

- * `csv` - transform table data to csv `format`
- * `export` - write output to local file
- * `grep` - `filter` output by pattern
- * `head` - take first n lines
- * `tail` - take last n lines

In addition to above built-**in** filters, **any** of the available system binaries can be used **as** filters **and** will receive the command output **as** stdin

15.2.1.4 Filters

You can pipe command output through one or more filters using the `|` (pipe) symbol. For example, `active Foo:Bar | csv | export ~/my_foos.csv`. If the filter is not recognized as a built-in filter, Daml Shell uses the system binary of the same name as the filter if such a binary exists.

15.2.2 Configuration

You can configure Daml Shell via CLI arguments, environment variables, a configuration file, or interactively using the `set` command.

15.2.2.1 Command line arguments

To see available command line options, run Daml Shell with the `--help` flag:

```
Usage: daml-shell [options]

-h, --help                prints this usage text
--config <file>           HOCON config file with settings as key-value pairs
--wildcard-char <char>    wildcard character used to abbreviate identifiers.
↳ Default: "..."
--identifier-hash-length <length>
                           Number of characters to render for hashes inside
↳ identifiers. Default: 20
--full-identifiers        Disable identifier shortening.
--identifier-trim-location <leading|middle|trailing>
                           Where to trim long identifiers. Default: "trailing"
--disable-color           Disable ANSI colored output.
--postgres-host <host>    Postgres host to connect to. Implies --connect.
↳ Default: "localhost"
--postgres-port <port>    Postgres port to connect to. Implies --connect.
↳ Default: 5432
--postgres-username <username>
                           Postgres username to connect with. Implies --connect.
↳ Default: "postgres"
--postgres-password <password>
                           Postgres password to connect with. Implies --connect.
↳ Default: none
--postgres-database <name>
                           Postgres database to connect to. Implies --connect.
↳ Default: "postgres"
--postgres-tls-mode <Disable|VerifyCA|VerifyFull>
                           TLS mode for Postgres connection. Implies --connect.
↳ Default: "Disable"
--postgres-tls-cafile <path>
                           Path to the TLS CA file for Postgres connection.
↳ Implies --connect. Default: none
--postgres-tls-cert <path>
                           Path to the TLS certificate file for Postgres
↳ connection. Implies --connect. Default: none
--postgres-tls-key <path>
                           Path to the TLS key file for Postgres connection.
↳ Implies --connect. Default: none
--connect                 Auto-connect to the database on startup.
```

If you specify a `--postgres-*` flag, Daml Shell will automatically connect to the database on startup.

15.2.2.2 Configuration file

You can set Daml Shell parameters in a reusable configuration file in HOCON (a JSON superset) using the flag `--config <filename>`.

Example file content:

```
# file: application.conf
oldest = "start"
latest = "end"
identifier-hash-length = 20
wildcard-char = "..."
identifier-trim-location = "trailing"
full-identifiers = false
disable-color = false
postgres-host = "localhost"
postgres-port = 5432
postgres-username = "postgres"
postgres-password = "mypassword"
postgres-database = "postgres"
postgres-tls-mode = "Disable"
```

15.2.2.3 Interactive configuration

You can configure settings interactively using the `set` command. Example:

```
> set identifier-hash-length full
Disabled identifier shortening
```

Type `help set` or `help set <setting>` to learn more about specific settings.

15.2.3 Usage

This section provides some basic usage examples.

15.2.3.1 Connecting

Daml Shell leverages PQS as its datastore and connects using JDBC. You can set connection parameters via configuration parameters or interactively using a JDBC URL. For more information, see [Configuration](#)

To connect interactively, enter the JDBC URL of your PQS PostgreSQL database. For example:

```
> connect jdbc:postgresql://localhost/postgres?user=postgres&password=postgres
```

The status bar shows the connected status, the session offset range, and the datastore offset range.

15.2.3.2 Offsets

By default, offsets have leading zeroes removed. To see all identifiers in full, including contract ID hashes, run `set identifier-hash-length full` or set a custom length limit for hashes by running, for example, `set identifier-hash-length 15`.

Depending on the ledger implementation, offsets may be in hexadecimal format.

The available offset range from the datastore is specified in the `Datastore range` status field. The offset range for Daml Shell to use to display payload counts and summaries is specified in the `Session range` status field.

You can move to different offsets by using the `go` command, which is an alias for `set latest`. `go -2` (go backward two offsets), `go +2` (go forward two offsets), `go forward` (alias `go next`), `go back` (alias `go backward`), `go start`, and `go end` are all examples of valid commands.

The `net-changes` command summarizes the changes effected by the transaction at the current offset. The `net-changes` command also accepts a `target offset` argument, or two `offset` arguments to compare between (see `help net-changes`).

```
> net-changes
+6 myproject:PingPong:Cash
-6 myproject:PingPong:CashTransferProposal
+6 myproject:PingPong:IAsset
-6 myproject:PingPong:IAssetTransferProposal
```

15.2.3.3 Summary information

Commands such as `active`, `archives`, `creates`, and `exercises` can be used without argument to see payload counts by fully qualified identifier names. For details, run `help <command>`.

```
> active
```

Identifier	Type	Count
myproject:PingPong:Cash	Template	12
myproject:PingPong:IAsset	Interface	12
myproject:PingPong:IBounceable	Interface	102
myproject:PingPong:Ping	Template	102

15.2.3.4 Payloads by fully qualified name

Specify a fully qualified name (FQN) with the command `active`, `archives`, `creates`, or `exercises` to list all applicable payloads for that FQN.

To return payloads from a particular package only, include the package name in the FQN:

```
> active myproject:PingPong:Ping
```

If you omit the package name, payloads from all package names are returned, as long as they have the same name.

```
> active PingPong:Ping
```

Created at	Contract ID	Contract Key	Payload	
8	0022e89289bda36...		label: one	
Alice::12209038d324bf70625c580267d5957cb4c4c03bb7bce294713b48151a4a088afd3b			owner:	
a	0093dce322a08c8...		label: one copy updated	
Alice::12209038d324bf70625c580267d5957cb4c4c03bb7bce294713b48151a4a088afd3b			owner:	

The auto-completion provides both FQN variants (with and without package name).

15.2.3.5 Filtering with `where` clauses

To refine your queries when listing contracts, you can use `where` clauses to filter on specific payload fields. `where` clauses use a SQL-like syntax for conditionals and are supported for the `active`, `creates`, `archives`, and `exercises` commands.

To access nested fields, use dot notation: `parent.child.value`

Comparison operators

- = Equal to
- != Not equal to
- > Greater than
- >= Greater than or equal to
- < Less than
- <= Less than or equal to
- like Used for pattern matching, % serves as a wildcard character

Logical operators

- and: Both conditions must be satisfied
- or: Either condition may be satisfied

You can use parentheses to group conditions and direct the order of evaluation.

Type casting

To ensure proper comparison, you can optionally cast fields to a specific type using the `::` operator. The available casting types are `numeric`, `timestamp`, and `text`.

Field values are sorted and compared lexicographically if no cast is specified.

where clause examples

Here are some examples of how to use `where` clauses in commands:

Filter by a string pattern:

```
> active where owner like Alice%
```

Lists contracts where the `owner` field starts with the string `Alice`.

Filter by a nested numeric field:

```
> active where deeply.nested.value :: numeric > 1000
```

Lists contracts where the nested field `value` is greater than 1000.

Filter with exact string match (note the use of double quotes):

```
> active where label = "loren ipsum"
```

Lists contracts where the `label` field is exactly `loren ipsum`. Use double quotes with values that contain whitespace characters.

Combine different conditions:

```
> active where (owner like Bob% or value :: numeric < 100) and myfield = myvalue
```

Lists contracts where the `owner` starts with `Bob` or the `value` is less than 100, and `myfield` is `myvalue`.

15.2.3.6 Contract lookup

You can look up contracts by contract ID. Interface views are also displayed, if any.

The contract ID can be copied with the wildcard character (here `*`) included. The wildcard character will be expanded to any matching ID.

```
> contract 005188b40...
```

Identifier	myproject:PingPong:Ping	
Type	Template	
Created at	a (not yet active)	
Archived at	<active>	
Contract ID	005188b40f981533f8f5...	

(continues on next page)

(continued from previous page)

Event ID	#1220731030eb9c81d0d0...:1	□
↩		
Contract Key		□
↩		
Payload	label: Copy of: this contract supersedes the original contact	□
↩		
	owner:□	
↩	Alice::1220b93eaba17d8da363ce7ef1b57d8494910ed4d7c99d2b33887f54832dbb77b5da

↩		
Contract Key		□
↩		
Payload	ilabel: View of: Copy of: this contract supersedes the original	□
↩	contact	

You can also compare two contracts in a diff-style output format using the `compare-contracts <id1> <id2>` command.

15.2.3.7 Transaction lookup

You can look up transactions by either transaction ID or offset, by running `transaction <transaction-id>` or `transaction at <offset>`, respectively. Note the `at` syntax when looking up by offset.

To display the current transaction at the head of the session offset range, run `transaction`.

The `transaction` command shows which contracts were created, which were archived, and what choices were exercised. It also displays the event ID for each of those events, as well as contract IDs and package names.

15.2.3.8 Exercise lookup

Exercised choices can be looked up in the same manner as contracts, except that exercises are looked up by their event ID rather than by a contract ID. The commands for summaries and lookups mirror the functionality available for contracts.

For example, you can look up exercise counts by FQN:

> exercises

Identifier	Type	Count
myproject:PingPong:AcceptIAssetTransferProposal	Consuming	12
myproject:PingPong:ChangeLabel	Consuming	1
myproject:PingPong:Copy	Non-consuming	1

You can look up exercises for a specific choice:

> exercises PingPong:AcceptIAssetTransferProposal

Offset	Contract ID	Argument	Result
7b	00604362bf43678ba849...		
004ddb65e00c8210d978fa13503d877e33d3d83dccc0addea759db1063c089412ca0212205b8a98e1b219436

15.2.4 Transforming and exporting command output

You can convert tabular output to CSV by piping it through the `csv` filter:

```
> active PingPong:Ping | csv
```

You can then write this output to a file by piping it through the `export` filter:

```
> active PingPong:Ping | csv | export ~/my_pings.csv
```

The `export` filter writes any command output to the specified file. You can use it without the `csv` filter.

15.2.4.1 Setting offset bounds

The output of `creates` [`<fqcn>`] and `archives` [`<fqcn>`] can be bounded by `set oldest` (for the lower bound) and `set latest` (for the upper bound). `go` is an alias for `set latest`.

15.2.4.2 Finding transactions that created or archived a contract

Once you know the offsets that a contract was created at (for example, by using the `archives` command), you can look up the relevant transactions using the `transaction at <offset>` command.

15.2.5 FAQ

15.2.5.1 Why don't I see any archived contracts?

If you don't see any archived contracts, PQS might be configured to seed the database from the ACS, which does not include historical offsets, archived contracts, or exercised choices.

To see pre-existing archived contracts, seed the database from the `Transaction Stream` or `Transaction Tree Stream`.

For best results, set `--pipeline-ledger-start` to `Genesis` when running PQS for the first time (refer to the [PQS documentation](#) or `--help` output).

15.2.5.2 Why don't I see any choices?

Choices are only visible on the Ledger API's `Transaction Tree Stream`. Set `--pipeline-datasource` to `TransactionTreeStream` when running PQS (refer to the [PQS documentation](#) or `--help` output).

If you still don't see choices, see [Why don't I see any archived contracts?](#)

15.2.5.3 Why don't I see any interface views?

Interfaces are only visible on the Ledger API's `Transaction Stream` or `ACS` (not the `Transaction Tree Stream`).

Set `--pipeline-datasource` to `TransactionStream` when running PQS (refer to the [PQS documentation](#) or `--help` output).

15.2.5.4 Why do all contracts show the same ledger offset?

See [Why don't I see any archived contracts?](#)

15.3 Canton Console

15.3.1 Introduction

Canton offers a console where you can run administrative or debugging commands.

When you run the Sandbox using `daml start` or `daml sandbox`, you are effectively starting an in-memory instance of Canton with a single sync domain and a single participant.

As such, you can interact with the running Sandbox using the console, just like you would in a production environment.

The purpose of this page is to give a few pointers on how the console can be used to interact with a running Sandbox. For an in-depth guide on how to use this tool against a production, staging or testing environment, [consult the main documentation for the Canton console](#).

15.3.2 Run the Canton Console Against the Sandbox

Once you have a Sandbox running locally (for example after running `daml start` or `daml sandbox`) you can start the console with the following command (in a separate terminal):

```
daml canton-console
```

Once the console starts (it might take some time the first time) you can quit the session by running the `exit` command.

15.3.3 Built-in Documentation

The Canton console comes with built-in documentation. You can use the `help` command to get online documentation for top-level commands. Many objects in the console also have further built-in help that you can access by invoking the `help` method on them.

For example, you can ask for help on the `health` object by typing:

```
health.help
```

Or go more in depth about specific items within that object as in the following example:

```
health.help("status")
```

15.3.4 Interact With the Sandbox

One of the objects available in the Canton console represents the Sandbox itself. The object is called `sandbox` and you can use it to interact with the Sandbox. For example, you can list the DARs loaded on the Sandbox by running the following command:

```
sandbox.dars.list()
```

Among the various features available as part of the console, you can manage parties and packages, check the health of the Sandbox, perform pruning operations and more. Consult the built-in documentation mentioned above and [the main documentation for the Canton console](#) to learn about further capabilities.

15.4 Deploy to a Generic Daml Ledger

Daml ledgers expose a unified administration API. This means that deploying to a Daml ledger is no different from deploying to your local sandbox.

To deploy to a Daml ledger, run the following command from within your Daml project:

```
$ daml deploy --host=<HOST> --port=<PORT> --access-token-file=<TOKEN-FILE>
```

where `<HOST>` and `<PORT>` is the hostname and port your ledger is listening on, which defaults to port 6564. The `<TOKEN-FILE>` is needed if your sandbox runs with [authorization](#) and needs to contain a JWT token with an `admin` claim. If your sandbox is not setup to use any authentication it can be omitted.

Instead of passing `--host`, `--port` and `--access-token-file` flags to the command above, you can add the following section to the project's `daml.yaml` file:

```
ledger:
  host: <HOSTNAME>
  port: <PORT>
  access-token-file: <PATH TO ACCESS TOKEN FILE>
```

The `daml deploy` command will

1. upload the project's compiled DAR file to the ledger. This will make the Daml templates defined in the current project available to the API users of the sandbox.
2. allocate the parties specified in the project's `daml.yaml` on the ledger if they are missing.

For additional interactions with the ledger, use the `daml ledger` command. Try running `daml ledger --help` to get a list of available ledger commands:

```
$ daml ledger --help
Usage: daml ledger COMMAND
Interact with a remote Daml ledger. You can specify the ledger in daml.yaml
with the ledger.host and ledger.port options, or you can pass the --host and
--port flags to each command below. If the ledger is authenticated, you should
pass the name of the file containing the token using the --access-token-file
```

(continues on next page)

(continued from previous page)

```
flag or the `daml.access-token-file` field in daml.yaml.
```

Available options:

```
-h, --help          Show this help text
```

Available commands:

```
list-parties        List parties known to ledger
allocate-parties    Allocate parties on ledger if they don't exist
upload-dar          Upload DAR file to ledger
fetch-dar           Fetch DAR from ledger into file
metering-report     Report on Ledger Use
```

15.4.1 Connect via TLS

To connect to the ledger via TLS, pass `--tls` to the various commands. If your ledger supports or requires mutual authentication you can pass your client key and certificate chain files via `--pem client_key.pem --crt client.crt`. Finally, you can use a custom certificate authority for validating the server certificate by passing `--cacrt server.crt`. If `--pem`, `--crt` or `--cacrt` are specified TLS is enabled automatically so `--tls` is redundant.

15.4.2 Configure Request Timeouts

You can configure the timeout used on API requests by passing `--timeout=N` to the various `daml ledger` commands and `daml deploy` which will set the timeout to N seconds. Note that this is a per-request timeout not a timeout for the whole command. That matters for commands like `daml deploy` that consist of multiple requests.

15.5 Experiment: Daml REPL (Deprecated)

Warning: Since Daml 2.9.0, `daml repl` is deprecated. It will be removed in Daml 3.0.

The Daml REPL allows you to use the [React to Off-Ledger Events: Daml Script](#) API interactively. This is useful for debugging and for interactively inspecting and manipulating a ledger.

15.5.1 Usage

First create a new project based on the `script-example` template. Take a look at the documentation for [React to Off-Ledger Events: Daml Script](#) for details on this template.

```
daml new script-example --template script-example # create a project called
↳ script-example based on the template
cd script-example # switch to the new project
```

Now, build the project and start [Test: Daml Sandbox](#), the in-memory ledger included in the SDK. Note that we are starting Sandbox in wallclock mode. Static time is not supported in `daml repl`.

```
daml build
daml sandbox --wall-clock-time --port=6865 --dar .daml/dist/script-example-0.0.1.
↳ dar
```

Now that the ledger has been started, you can launch the REPL in a separate terminal using the following command.

```
daml repl --ledger-host=localhost --ledger-port=6865 .daml/dist/script-example-0.
↳ 0.1.dar --import script-example
```

The `--ledger-host` and `--ledger-port` parameters point to the host and port your ledger is running on. In addition to that, you also need to pass in the name of a DAR containing the templates and other definitions that will be accessible in the REPL. We also specify that we want to import all modules from the `script-example` package. If your modules provide colliding definitions you can also import modules individually from within the REPL. Note that you can also specify multiple DARs and they will all be available.

You should now see a prompt looking like

```
daml>
```

You can think of this prompt like a line in a `do`-block of the `Script` action. Each line of input has to have one of the following two forms:

1. An expression `expr` of type `Script a` for some type `a`. This will execute the script and print the result if `a` is an instance of `Show` and not `()`.
2. A pure expression `expr` of type `a` for some type `a` where `a` is an instance of `Show`. This will evaluate `expr` and print the result. If you are only interest in pure expressions you can also use Daml REPL [without connecting to a ledger](#).
3. A binding of the form `pat <- expr` where `pat` is pattern, e.g., a variable name `x` to bind the result to and `expr` is an expression of type `Script a`. This will execute the script and match the result against the pattern `pat` bindings the matches to the variables in the pattern. You can then use those variables on subsequent lines.
4. A `let` binding of the form `let pat = y`, where `pat` is a pattern and `y` is a pure expression or `let f x = y` to define a function. The bound variables can be used on subsequent lines.
5. Next to Daml code the REPL also understands REPL commands which are prefixed by `:.` Enter `:help` to see a list of supported REPL commands.

First create two parties: A party with the display name "Alice" and the party id "alice" and a party with the display name "Bob" and the party id "bob".

```
daml> alice <- allocatePartyWithHint "Alice" (PartyIdHint "alice")
daml> bob <- allocatePartyWithHint "Bob" (PartyIdHint "bob")
```

Next, create a `CoinProposal` from Alice to Bob

```
daml> submit alice (createCmd (CoinProposal (Coin alice bob)))
```

As Bob, you can now get the list of active `CoinProposal` contracts using the `query` function. The `debug : Show a => a -> Script ()` function can be used to print values.

```
daml> proposals <- query @CoinProposal bob
daml> debug proposals
[Daml.Script:39]: [(<contract-id>,CoinProposal {coin = Coin {issuer = 'alice',
↳ owner = 'bob'}})]
```

Finally, accept all proposals using the `forA` function to iterate over them.

```
daml> forA proposals $ \(contractId, _) -> submit bob (exerciseCmd contractId
↪Accept)
```

Using the `query` function we can now verify that there is one `Coin` and no `CoinProposal`:

```
daml> coins <- query @Coin bob
daml> debug coins
[Daml.Script:39]: [(<contract-id>,Coin {issuer = 'alice', owner = 'bob'})]
daml> proposals <- query @CoinProposal bob
[Daml.Script:39]: []
```

To exit `daml repl` press `Control-D`.

15.5.2 What Is in Scope at the Prompt?

In the prompt, all modules from DALFs specified in `--import` are imported automatically. In addition to that, the `Daml.Script` module is also imported and gives you access to the Daml Script API.

You can use the commands `:module + ModA ModB ...` to import additional modules and `:module - ModA ModB ...` to remove previously added imports. Modules can also be imported using regular import declarations instead of `module +`. The command `:show imports` lists the currently active imports.

```
daml> import DA.Time
daml> debug (days 1)
```

15.5.3 Using Daml REPL Without a Ledger

If you are only interested in pure expressions, e.g., because you want to test how some function behaves you can omit the `--ledger-host` and `-ledger-port` parameters. Daml REPL will work as usual but any attempts to call Daml Script APIs that interact with the ledger, e.g., `submit` will result in the following error:

```
daml> java.lang.RuntimeException: No default participant
```

15.5.4 Connecting via TLS

You can connect to a ledger that requires TLS by passing `--tls`. A custom root certificate used for validating the server certificate can be set via `--cacrt`. Finally, you can also enable client authentication by passing `--pem client.key --crt client.crt`. If `--cacrt` or `--pem` and `--crt` are passed TLS is automatically enabled so `--tls` is redundant.

15.5.5 Connection to a Ledger With Authorization

If your ledger requires an authorization token you can pass it via `--access-token-file`.

15.5.6 Using Daml REPL to Convert to JSON

Using the `:json` command you can encode serializable Daml expressions as JSON. For example using the definitions and imports from above:

```
daml> :json days 1
{"microseconds":864000000000}
daml> :json map snd coins
[{"issuer":"alice","owner":"bob"}]
```

15.6 Write: Daml Studio

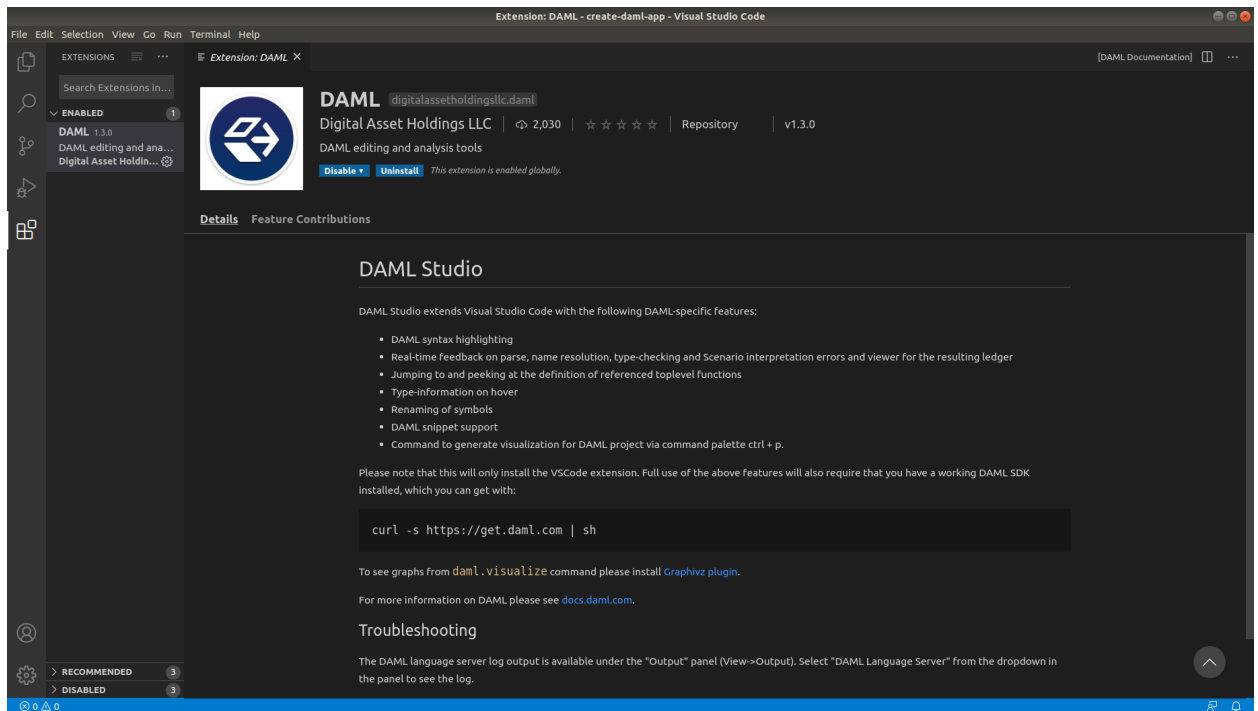

Daml Studio is an integrated development environment (IDE) for Daml. It is an extension on top of [Visual Studio Code](#) (VS Code), a cross-platform, open-source editor providing a [rich code editing experience](#).

15.6.1 Install

Daml Studio is included in [the Daml SDK](#).

15.6.2 Create Your First Daml File

1. Start Daml Studio by running `daml studio` in the current project.
This command starts Visual Studio Code and (if needs be) installs the Daml Studio extension, or upgrades it to the latest version.
2. Make sure the Daml Studio extension is installed:
 1. Click on the Extensions icon at the bottom of the VS Code sidebar.
 2. Click on the Daml Studio extension that should be listed on the pane.

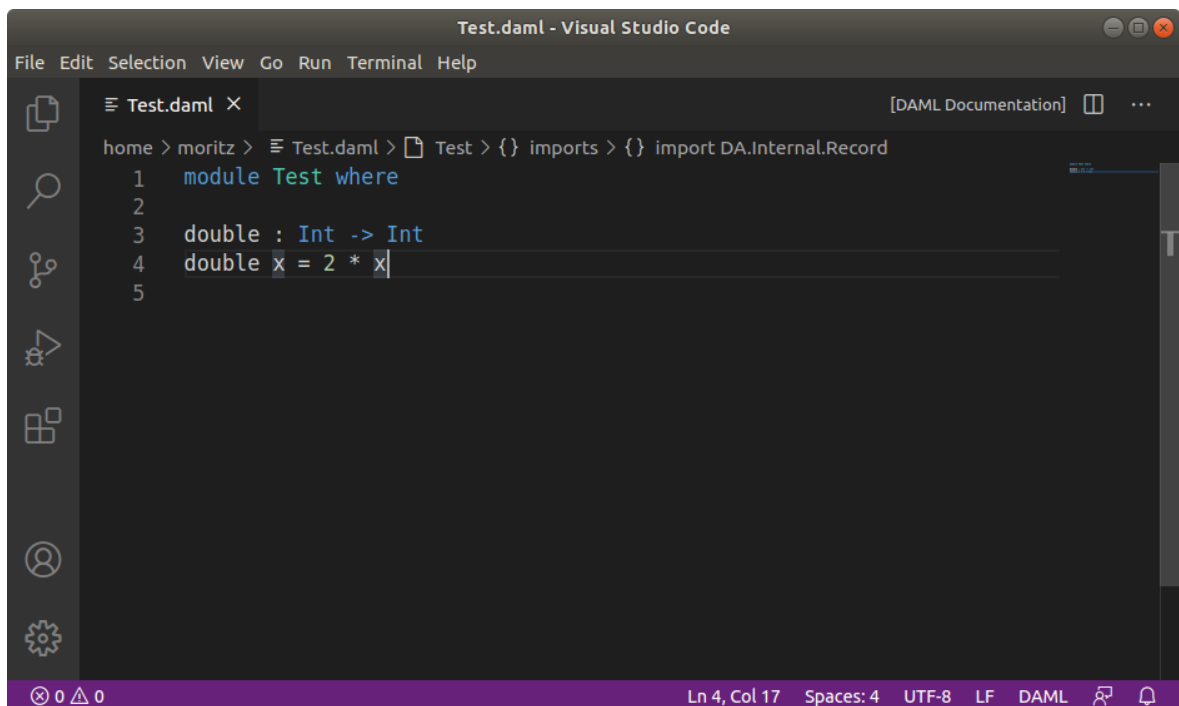

3. Open a new file (⇧N) and save it (⇧S) as `Test.daml`.
4. Copy the following code into your file:

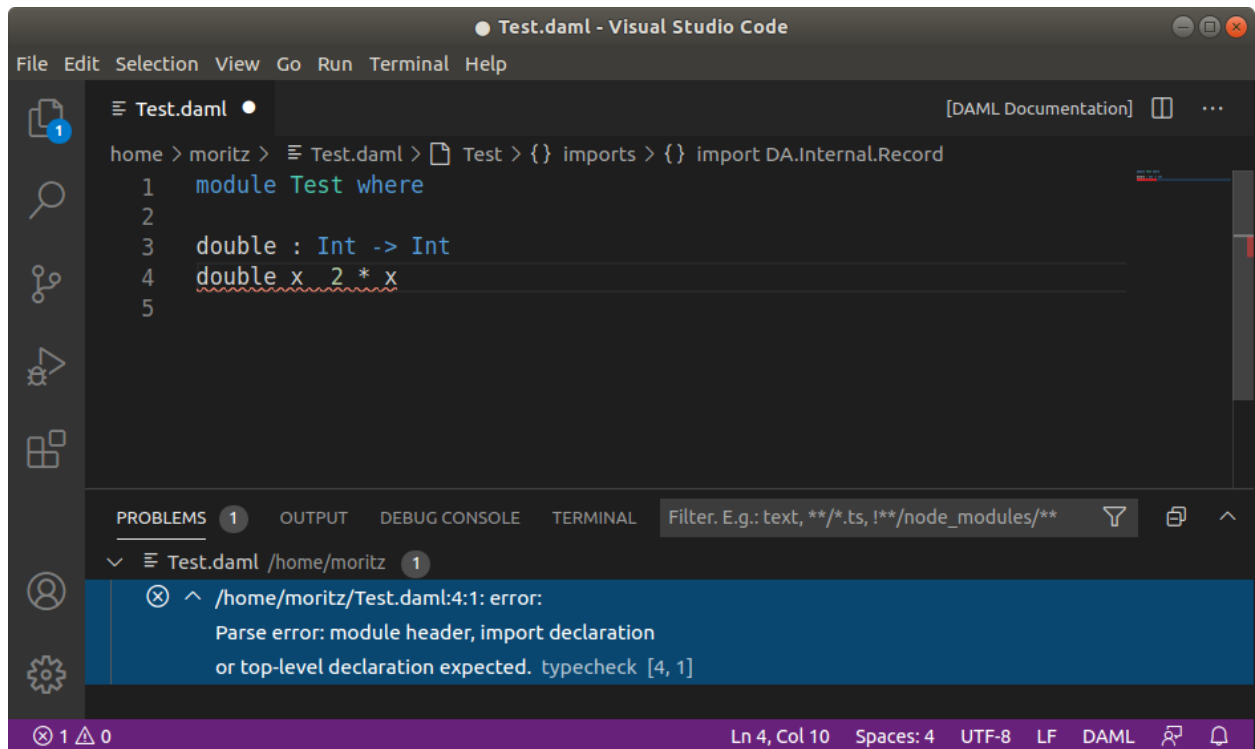

```
module Test where

double : Int -> Int
double x = 2 * x
```

Your screen should now look like the image below.

5. Introduce a parse error by deleting the `=` sign and then clicking the  symbol on the lower-left corner. Your screen should now look like the image below.

6. Remove the parse error by restoring the = sign.

We recommend reviewing the [Visual Studio Code documentation](#) to learn more about how to use it. To learn more about Daml, see [Language Reference](#).

15.6.3 Supported Features

Visual Studio Code provides many helpful features for editing Daml files and we recommend reviewing [Visual Studio Code Basics](#) and [Visual Studio Code Keyboard Shortcuts for OS X](#). The Daml Studio extension for Visual Studio Code provides the following Daml-specific features:

15.6.3.1 Symbols and Problem Reporting

Use the commands listed below to navigate between symbols, rename them, and inspect any problems detected in your Daml files. Symbols are identifiers such as template names, lambda arguments, variables, and so on.

Command	Shortcut (OS X)
Go to Definition	F12
Peek Definition	 F12
Rename Symbol	F2
Go to Symbol in File	 O
Go to Symbol in Workspace	 T
Find all References	 F12
Problems Panel	 M

Note: You can also start a command by typing its name into the command palette (press P or

F1). The command palette is also handy for looking up keyboard shortcuts.

Note:

[Rename Symbol](#), [Go to Symbol in File](#), [Go to Symbol in Workspace](#), and [Find all References](#) work on: choices, record fields, top-level definitions, let-bound variables, lambda arguments, and modules

[Go to Definition](#) and [Peek Definition](#) work on: top-level definitions, let-bound variables, lambda arguments, and modules

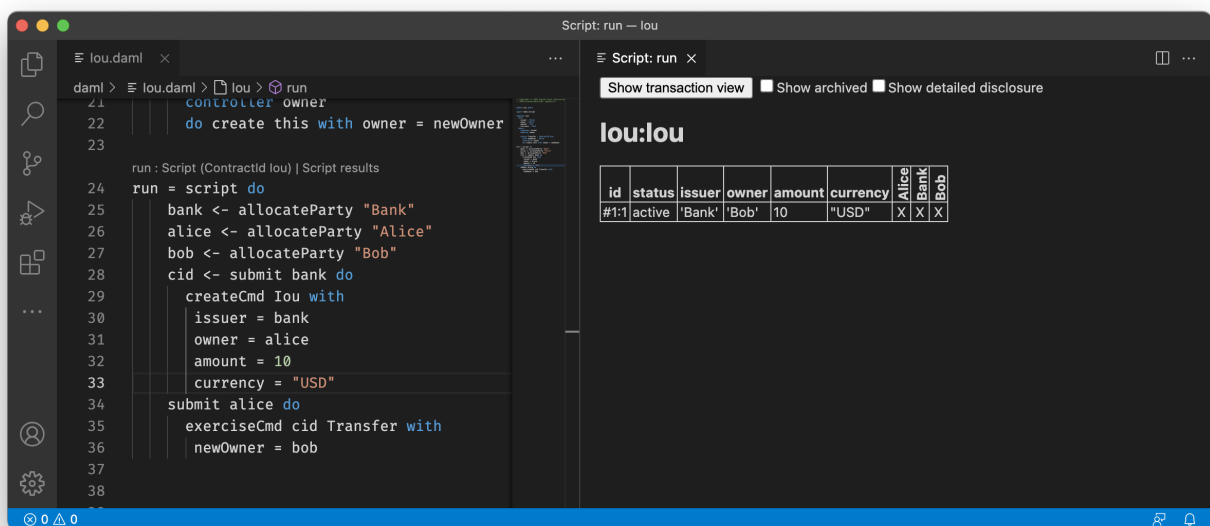

15.6.3.2 Hover Tooltips

You can [hover](#) over most symbols in the code to display additional information such as its type.

15.6.3.3 Daml Script Results

Top-level declarations of type `Script` are decorated with a `Script` results code lens. You can click on the code lens to inspect the execution transaction graph and the active contracts.

For the script from the `Iou` module, you get the following table displaying all contracts that are active at the end of the script. The first column displays the contract id. The columns afterwards represent the fields of the contract and finally you get one column per party with an `X` if the party can see the contract or a `-` if not.

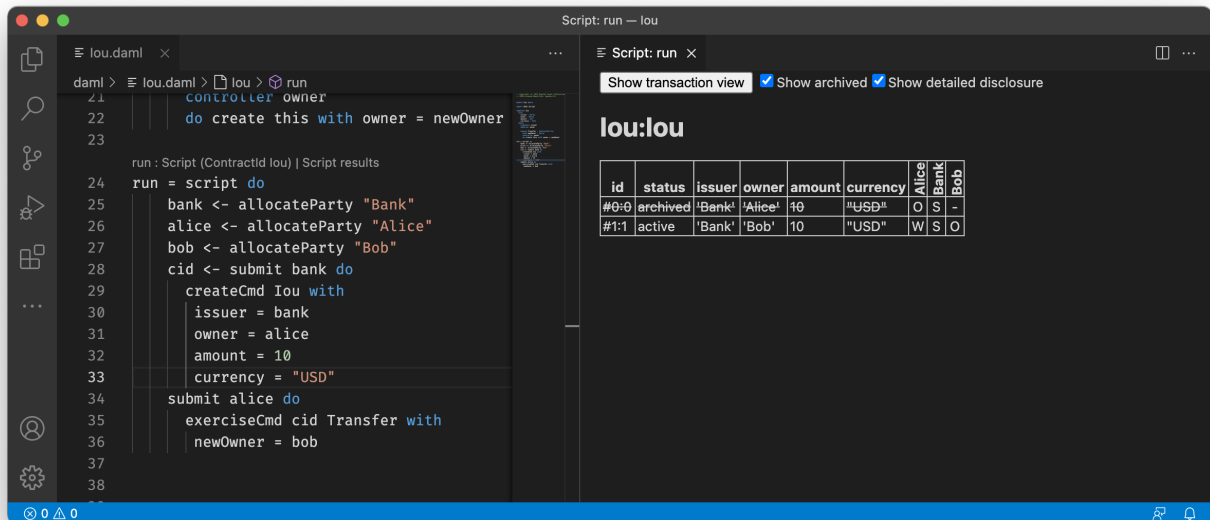

If you want more details, you can click on the *Show archived* checkbox, which extends the table to include archived contracts, and on the *Show detailed disclosure* checkbox, which displays why the contract is visible to each party, based on four categories:

1. S, the party sees the contract because they are a signatory on the contract.
2. O, the party sees the contract because they are an observer on the contract.

3. `W`, the party sees the contract because they witnessed the creation of this contract, e.g., because they are an actor on the `exercise` that created it.
4. `D`, the party sees the contract because they have been divulged the contract, e.g., because they witnessed an exercise that resulted in a `fetch` of this contract.

For details on the meaning of those four categories, refer to the [Daml Ledger Model](#). For the example above, the resulting table looks as follows. You can see the archived `Bank` contract and the active `Bank` contract whose creation `Alice` has witnessed by virtue of being an actor on the `exercise` that created it.

If you want to see the detailed transaction graph you can click on the `Show transaction view` button. The transaction graph consists of transactions, each of which contain one or more updates to the ledger, that is creates and exercises. The transaction graph also records fetches of contracts.

For example a script for the `Iou` module looks as follows:

Each transaction is the result of executing a step in the script. In the image below, the transaction `#0` is the result of executing the first line of the script (line 20), where the `Iou` is created by the bank. The following information can be gathered from the transaction:

- The result of the first script transaction `#0` was the creation of the `Iou` contract with the arguments `bank`, `10`, and `"USD"`.
- The created contract is referenced in transaction `#1`, step `0`.
- The created contract was consumed in transaction `#1`, step `0`.
- A new contract was created in transaction `#1`, step `1`, and has been divulged to parties 'Alice', 'Bob', and 'Bank'.
- At the end of the script only the contract created in `#1:1` remains.
- The return value from running the script is the contract identifier `#1:1`.
- And finally, the contract identifiers assigned in script execution correspond to the script step that created them (e.g. `#1`).

You can navigate to the corresponding source code by clicking on the location shown in parenthesis (e.g. `Iou:25:12`, which means the `Iou` module, line 25 and column 1). You can also navigate between transactions by clicking on the transaction and contract ids (e.g. `#1:0`).

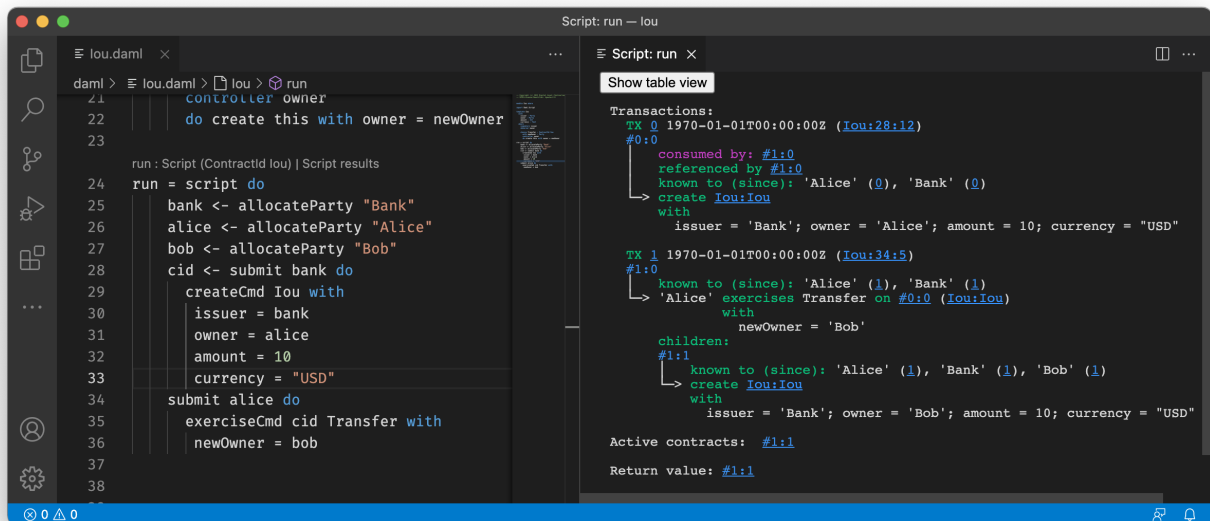

Fig. 1: Script results

15.6.3.4 Daml Snippets

You can automatically complete a number of snippets when editing a Daml source file. By default, hitting `^–Space` after typing a Daml keyword displays available snippets that you can insert.

To define your own workflow around Daml snippets, adjust your user settings in Visual Studio Code to include the following options:

```
{
  "editor.tabCompletion": true,
  "editor.quickSuggestions": false
}
```

With those changes in place, you can simply hit `Tab` after a keyword to insert the code pattern.

You can develop your own snippets by following the instructions in [Creating your own Snippets](#) to create an appropriate `daml.json` snippet file.

15.6.4 Common Script Errors

During Daml execution, errors can occur due to exceptions (e.g. use of `abort`, or division by zero), or due to authorization failures. You can expect to run into the following errors when writing Daml.

When a runtime error occurs in a script execution, the script result view shows the error together with the following additional information, if available:

Location of the failed commit If the failing part of the script was a `submitCmd`, the source location of the call to `submitCmd` will be displayed.

Stack trace A list of source locations that were encountered before the error occurred. The last encountered location is the first entry in the list.

Ledger time The ledger time at which the error occurred.

Partial transaction The transaction that is being constructed, but not yet committed to the ledger.

Committed transaction Transactions that were successfully committed to the ledger prior to the error.

Trace Any messages produced by calls to `trace` and `debug`.

15.6.4.1 Abort, Assert, and Debug

The `abort`, `assert` and `debug` inbuilt functions can be used in updates and scripts. All three can be used to output messages, but `abort` and `assert` can additionally halt the execution:

```
abortTest = script do
  debug "hello, world!"
  abort "stop"
```

```
Script execution failed:
  Unhandled exception:  DA.Exception.GeneralError:GeneralError with
```

(continues on next page)

(continued from previous page)

```

        message = "stop"

Ledger time: 1970-01-01T00:00:00Z

Trace:
    "hello, world!"

```

15.6.4.2 Missing Authorization on Create

If a contract is being created without approval from all authorizing parties the commit will fail. For example:

```

template Example
  with
    party1 : Party; party2 : Party
  where
    signatory party1
    signatory party2

example = script do
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"
  alice `submit` createCmd Example with
    party1 = alice
    party2 = bob

```

Execution of the example script fails due to ‘Bob’ being a signatory in the contract, but not authorizing the create:

```

Script execution failed:
  #0: create of CreateAuthFailure:Example at unknown source
      failed due to a missing authorization from 'Bob'

Ledger time: 1970-01-01T00:00:00Z

Partial transaction:
  Sub-transactions:
    #0
    ↳ Alice creates CreateAuthFailure:Example
      with
        party1 = 'Alice'; party2 = 'Bob'

```

To create the `Example` contract one would need to bring both parties to authorize the creation via a choice, for example ‘Alice’ could create a contract giving ‘Bob’ the choice to create the ‘Example’ contract.

15.6.4.3 Missing Authorization on Exercise

Similarly to creates, exercises can also fail due to missing authorizations when a party that is not a controller of a choice exercises it.

```
template Example
  with
    owner : Party
    friend : Party
  where
    signatory owner
    observer friend

    choice Consume : ()
      controller owner
      do return ()

    choice Hello : ()
      controller friend
      do return ()

example = script do
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"
  cid <- alice `submit` createCmd Example with
    owner = alice
    friend = bob
  bob `submit` exerciseCmd cid Consume
```

The execution of the example script fails when 'Bob' tries to exercise the choice 'Consume' of which he is not a controller

```
Script execution failed:
  #1: exercise of Consume in ExerciseAuthFailure:Example at unknown source
      failed due to a missing authorization from 'Alice'

Ledger time: 1970-01-01T00:00:00Z

Partial transaction:
  Failed exercise:
    exercises Consume on #0:0 (ExerciseAuthFailure:Example)
    with
  Sub-transactions:
    0
    ↳ 'Alice' exercises Consume on #0:0 (ExerciseAuthFailure:Example)
      with

Committed transactions:
  TX #0 1970-01-01T00:00:00Z (unknown source)
  #0:0
  ↳ disclosed to (since): 'Alice' (#0), 'Bob' (#0)
  ↳ 'Alice' creates ExerciseAuthFailure:Example
    with
    owner = 'Alice'; friend = 'Bob'
```

From the error we can see that the parties authorizing the exercise ('Bob') is not a subset of the required controlling parties.

15.6.4.4 Contract Not Visible

Contract not being visible is another common error that can occur when a contract that is being fetched or exercised has not been disclosed to the committing party. For example:

```
template Example
  with owner: Party
  where
    signatory owner

    choice Consume : ()
      controller owner
      do return ()

example = script do
  alice <- allocateParty "Alice"
  bob <- allocateParty "Bob"
  cid <- alice `submit` createCmd Example with owner = alice
  bob `submit` exerciseCmd cid Consume
```

In the above script the ‘Example’ contract is created by ‘Alice’ and makes no mention of the party ‘Bob’ and hence does not cause the contract to be disclosed to ‘Bob’. When ‘Bob’ tries to exercise the contract the following error would occur:

```
Script execution failed:
  Attempt to fetch or exercise a contract not visible to the reading parties.
  Contract: #0:0 (NotVisibleFailure:Example)
  actAs: 'Bob'
  readAs:
  Disclosed to: 'Alice'

Ledger time: 1970-01-01T00:00:00Z

Partial transaction:

Committed transactions:
  TX #0 1970-01-01T00:00:00Z (unknown source)
  #0:0
  |   disclosed to (since): 'Alice' (#0)
  |> 'Alice' creates NotVisibleFailure:Example
      with
        owner = 'Alice'
```

To fix this issue the party ‘Bob’ should be made a controlling party in one of the choices.

15.6.5 Multi-Package Support

Following the Multi-Package support added to `daml build` ([see here](#)), Daml Studio also supports projects that utilize the `multi-package.yaml` file. You should become familiar with multi-package builds before continuing in this section. The Daml Studio Multi-IDE feature runs separate package environments for each package in your project, and allows cross-package jump-to-definition for any packages listed in a top level `multi-package.yaml` file.

15.6.5.1 Multi-package.yaml Location

Daml Studio only uses the `multi-package.yaml` file if it sits at the VS Code Workspace Root, that is, in the root directory in which Daml Studio was opened. If no `multi-package.yaml` is found, the cross-package jump-to-definition feature cannot jump to the real on-disk source code, however, other Multi-IDE features still work as normal.

15.6.5.2 Package Environments and Hot-Loading

The Multi-IDE runs a separate package environment for each package in the project, allowing the IDE to replicate properties such as dependencies, module-prefixes, and build-options of each package individually, without clashing with other packages in the project. A package's environment automatically reloads if its `daml.yaml` file changes, or any of the dependency DAR files change.

Note, however, that the Multi-IDE does not hold live copies of DARs, therefore any changes to a package that is a dependency of another package are not visible in that second package until you run `daml build`. You can run `daml build --all` to rebuild all relevant DARs. The IDE accounts for this and reloads environments as necessary.

Jumping to definition on non-local dependencies (those not listed in `multi-package.yaml`) also uses the correct environment, giving correct diagnostics for that package, and allowing further jumps down the stack. However, this can only jump to a package for which the source code is available, that is packages to which the DAR can be found in any of the following places:

- The `data-dependencies` field of the current package or any other packages known to the `multi-package.yaml`
- Under the added `dars` field in the `multi-package.yaml`, which is shown below:

```
packages:
- my-package
- libs/my-lib
dars:
# Given my-package depends on some DAR, which then depends on my-transitive-
↪dependency
- ./dars/my-transitive-dependency-1.0.0.dar
```

Adding DAR paths to this field has no effect on building, serving only for the IDE to jump to.

15.6.5.3 Multiple Daml SDK Versions

Separate package environments can run in different Daml SDK versions (though some features may not work correctly in versions ≤ 2.8). When opening a file, or jumping to a location in a package running a Daml version that is not currently installed, Daml Studio prompts you to install the missing Daml SDK, and then handles the installation, progress reporting, and cancellation within a notification.

15.6.5.4 Directory Environment Tools (direnv)

Tools like `direnv` are commonly used to set up dependencies and import environment variables for use with [environment variable interpolation support](#). To make this work in Daml Studio, you need a VSCode extension that sets this up for other extensions. In the case of `direnv` specifically (i.e. you have a `.envrc` file), we recommend using [this direnv extension by Martin Kühl](#), which we have verified is compatible. Other `direnv` extensions may not correctly pass environment information to the Daml Studio extension.

If the Daml extension detects a `.envrc` file, it recommends this extension within the IDE with the following message:

..code:

```
Found an .envrc file but the recommended direnv VSCode extension is not installed.
→ Daml IDE may fail to start due to missing environment variables.
Would you like to install the recommended direnv extension or attempt to continue ☐
→ without it?
```

It also provides a link to the extension on the VS Code extension marketplace.

15.6.5.5 Limitations in 2.10.0-rc

These limitations are for the Release Candidate only, not for the 2.10 full release.

Jumping to non-local dependencies does not currently retain the build-options and module-prefixes for that package. This means that if you jump to a dependency that requires either of these to build, the editor shows errors in the source code.

Some links in the Script Results tab may not resolve correctly cross-package.

Packages with symlinks between the `daml.yaml` and source files may not give correct intelligence.

15.6.5.6 Setting Multi-IDE SDK Version

The Multi-IDE selects the correct SDK version for each package you interact with. However the Multi-IDE itself runs from your most recently installed SDK version. You can override this using an additional `daml.yaml` file at the root of your project (next to the `multi-package.yaml`) containing only an SDK Version, as follows:

The root `daml.yaml` contains only the `sdk-version` field, as shown below. Note that Multi-IDE is only supported in 2.10+.

`sdk-version: 2.10.0`

This feature can also be used when Multi-IDE is inactive, as described below.

15.6.5.7 Deactivating Multi-IDE

The Multi-IDE feature can be deactivated by going to VSCode settings (`ctrl + ,`), searching for `Daml: Multi Package Ide Support`, and unticking the box. You do not need to restart your editor. If you are deactivating this feature due to a bug, please report it on the [forums](#).

15.7 Test: Daml Sandbox

The Daml Sandbox, or Sandbox for short, is a simple ledger implementation that enables rapid application prototyping by simulating a Daml Ledger.

You can start Sandbox together with [Navigator \(Deprecated\)](#) using the `daml start` command in a Daml project. This command will compile the Daml file and its dependencies as specified in the `daml.yaml`. It will then launch Sandbox passing the just obtained DAR packages. The script specified in the `init-script` field in `daml.yaml` will be loaded into the ledger. Finally, it launches the navigator connecting it to the running Sandbox.

It is possible to execute the Sandbox launching step in isolation by typing `daml sandbox`.

Sandbox can also be run manually as in this example:

```
$ daml sandbox --dar Main.dar --static-time
Starting Canton sandbox.
Listening at port 6865
Uploading .daml/dist/foobar-0.0.1.dar to localhost:6865
DAR upload succeeded.
Canton sandbox is ready.
```

Behind the scenes, Sandbox spins up a Canton ledger with an in-memory participant `sandbox` and an in-memory sync domain `local`. You can pass additional Canton configuration files via `-c`. This option can be specified multiple times and the resulting configuration files will be merged.

```
$ daml sandbox -c path/to/canton/config
```

15.7.1 Run With Authorization

By default, Sandbox accepts all valid ledger API requests without performing any request authorization.

To start Sandbox with authorization using [JWT-based](#) access tokens as described in the [Authorization documentation](#), create a config file that specifies the type of authorization service and the path to the certificate.

Listing 1: auth.conf

```
canton.participants.sandbox.ledger-api.auth-services = [{
  // type can be
  //   jwt-rs-256-crt
  //   jwt-es-256-crt
  //   jwt-es-512-crt
  //   jwt-rs-256-jwks with an additional url
  //   unsafe-jwt-hmac-256 with an additional secret
  type = jwt-rs-256-crt
  certificate = my-certificate.cert
}]
```

The settings under `auth-services` are described in detail in [API configuration documentation](#)

15.7.1.1 Generate JSON Web Tokens (JWT)

To generate access tokens for testing purposes, use the jwt.io web site.

15.7.1.2 Generate RSA keys

To generate RSA keys for testing purposes, use the following command

```
openssl req -nodes -new -x509 -keyout sandbox.key -out sandbox.crt
```

which generates the following files:

`sandbox.key`: the private key in PEM/DER/PKCS#1 format
`sandbox.crt`: a self-signed certificate containing the public key, in PEM/DER/X.509 Certificate format

15.7.1.3 Generate EC keys

To generate keys to be used with ES256 for testing purposes, use the following command

```
openssl req -x509 -nodes -days 3650 -newkey ec:<(openssl ecparam -name prime256v1) -keyout ecdsa256.key -out ecdsa256.crt
```

which generates the following files:

`ecdsa256.key`: the private key in PEM/DER/PKCS#1 format
`ecdsa256.crt`: a self-signed certificate containing the public key, in PEM/DER/X.509 Certificate format

Similarly, you can use the following command for ES512 keys:

```
openssl req -x509 -nodes -days 3650 -newkey ec:<(openssl ecparam -name secp521r1) -keyout ecdsa512.key -out ecdsa512.crt
```

15.7.2 Run With TLS

To enable TLS, you need to specify the private key for your server and the certificate chain. This enables TLS for both the Ledger API and the Canton Admin API. When enabling client authentication, you also need to specify client certificates which can be used by Canton's internal processes. Note that the identity of the application will not be proven by using this method, i.e. the `application_id` field in the request is not necessarily correlated with the CN (Common Name) in the certificate. Below, you can see an example config. For more details on TLS, refer to [Canton's documentation on TLS](#).

Listing 2: `tls.conf`

```
canton.participants.sandbox.ledger-api {
  tls {
    // the certificate to be used by the server
    cert-chain-file = "./tls/ledger-api.crt"
    // private key of the server
    private-key-file = "./tls/ledger-api.pem"
    // trust collection, which means that all client certificates will be
    ↪verified using the trusted
    // certificates in this store. if omitted, the JVM default trust store is
    ↪used.
    trust-collection-file = "./tls/root-ca.crt"
    // define whether clients need to authenticate as well (default not)
    client-auth = {
      // none, optional and require are supported
      type = require
      // If clients are required to authenticate as well, we need to provide a
    ↪client
      // certificate and the key, as Canton has internal processes that need to
    ↪connect to these
      // APIs. If the server certificate is trusted by the trust-collection, then
    ↪you can
      // just use the server certificates. Otherwise, you need to create separate
    ↪ones.
      admin-client {
        cert-chain-file = "./tls/admin-client.crt"
        private-key-file = "./tls/admin-client.pem"
      }
    }
  }
}
```

15.7.3 Command-line Reference

To start Sandbox, run: `daml sandbox [options] [-c canton.config]`.

To see all the available options, run `daml sandbox --help`. Note that this will show you the options of the Sandbox wrapper around Canton. To see options of the underlying Canton runner, use `daml sandbox --canton-help`.

15.7.4 Metrics

15.7.4.1 Enable and Configure Reporting

You can enable metrics reporting via Prometheus using the following configuration file.

Listing 3: metrics.conf

```
canton.monitoring.metrics.reporters = [{  
  type = prometheus  
  address = "localhost" // default  
  port = 9000 // default  
}]
```

For other options and more details refer to the [Canton documentation](#).

15.7.4.2 Types of Metrics

This is a list of type of metrics with all data points recorded for each. Use this as a reference when reading the list of metrics.

Gauge

An individual instantaneous measurement.

Counter

Number of occurrences of some event.

Meter

A meter tracks the number of times a given event occurred. The following data points are kept and reported by any meter.

```
<metric.qualified.name>.count: number of registered data points overall  
<metric.qualified.name>.m1_rate: number of registered data points per minute  
<metric.qualified.name>.m5_rate: number of registered data points every 5 minutes  
<metric.qualified.name>.m15_rate: number of registered data points every 15 minutes  
<metric.qualified.name>.mean_rate: mean number of registered data points
```

Histogram

An histogram records aggregated statistics about collections of events. The exact meaning of the number depends on the metric (e.g. timers are histograms about the time necessary to complete an operation).

```
<metric.qualified.name>.mean: arithmetic mean
<metric.qualified.name>.stddev: standard deviation
<metric.qualified.name>.p50: median
<metric.qualified.name>.p75: 75th percentile
<metric.qualified.name>.p95: 95th percentile
<metric.qualified.name>.p98: 98th percentile
<metric.qualified.name>.p99: 99th percentile
<metric.qualified.name>.p999: 99.9th percentile
<metric.qualified.name>.min: lowest registered value overall
<metric.qualified.name>.max: highest registered value overall
```

Histograms only keep a small *reservoir* of statistically relevant data points to ensure that metrics collection can be reasonably accurate without being too taxing resource-wise.

Unless mentioned otherwise all histograms (including timers, mentioned below) use exponentially decaying reservoirs (i.e. the data is roughly relevant for the last five minutes of recording) to ensure that recent and possibly operationally relevant changes are visible through the metrics reporter.

Note that `min` and `max` values are not affected by the reservoir sampling policy.

You can read more about reservoir sampling and possible associated policies in the [Dropwizard Metrics library documentation](#).

Timers

A timer records all metrics registered by a meter and by an histogram, where the histogram records the time necessary to execute a given operation (unless otherwise specified, the precision is nanoseconds and the unit of measurement is milliseconds).

Database Metrics

A `database metric` is a collection of simpler metrics that keep track of relevant numbers when interacting with a persistent relational store.

These metrics are:

```
<metric.qualified.name>.wait (timer): time to acquire a connection to the database
<metric.qualified.name>.exec (timer): time to run the query and read the result
<metric.qualified.name>.query (timer): time to run the query
<metric.qualified.name>.commit (timer): time to perform the commit
<metric.qualified.name>.translation (timer): if relevant, time necessary to turn serialized Daml-LF values into in-memory objects
```

15.7.4.3 List of Metrics

The following is a non-exhaustive list of selected metrics that can be particularly important to track. Note that not all the following metrics are available unless you run the sandbox with a PostgreSQL backend.

`daml.commands.delayed_submissions`

A meter. Number of delayed submissions (submission that have been evaluated to transaction with a ledger time farther in the future than the expected latency).

`daml.commands.failed_command_interpretations`

A meter. Number of commands that have been deemed unacceptable by the interpreter and thus rejected (e.g. double spends)

`daml.commands.submissions`

A timer. Time to fully process a submission (validation, deduplication and interpretation) before it's handed over to the ledger to be finalized (either committed or rejected).

`daml.commands.valid_submissions`

A meter. Number of submission that pass validation and are further sent to deduplication and interpretation.

`daml.commands.validation`

A timer. Time to validate submitted commands before they are fed to the Daml interpreter.

`daml.commands.input_buffer_capacity`

A counter. The capacity of the queue accepting submissions on the CommandService.

`daml.commands.input_buffer_length`

A counter. The number of currently pending submissions on the CommandService.

`daml.commands.input_buffer_delay`

A timer. Measures the queuing delay for pending submissions on the CommandService.

`daml.commands.max_in_flight_capacity`

A counter. The capacity of the queue tracking completions on the CommandService.

`daml.commands.max_in_flight_length`

A counter. The number of currently pending completions on the CommandService.

`daml.execution.get_lf_package`

A timer. Time spent by the engine fetching the packages of compiled Daml code necessary for interpretation.

`daml.execution.lookup_active_contract_count_per_execution`

A histogram. Number of active contracts fetched for each processed transaction.

`daml.execution.lookup_active_contract_per_execution`

A timer. Time to fetch all active contracts necessary to process each transaction.

`daml.execution.lookup_active_contract`

A timer. Time to fetch each individual active contract during interpretation.

`daml.execution.lookup_contract_key_count_per_execution`

A histogram. Number of contract keys looked up for each processed transaction.

`daml.execution.lookup_contract_key_per_execution`

A timer. Time to lookup all contract keys necessary to process each transaction.

`daml.execution.lookup_contract_key`

A timer. Time to lookup each individual contract key during interpretation.

`daml.execution.retry`

A meter. Overall number of interpretation retries attempted due to mismatching ledger effective time.

`daml.execution.total`

A timer. Time spent interpreting a valid command into a transaction ready to be submitted to the ledger for finalization.

`daml.index.db.connection.api.server.pool`

This namespace holds a number of interesting metrics about the connection pool used to communicate with the persistent store that underlies the index.

These metrics include:

- `daml.index.db.connection.api.server.pool.Wait` (timer): time spent waiting to acquire a connection
- `daml.index.db.connection.api.server.pool.Usage` (histogram): time spent using each acquired connection
- `daml.index.db.connection.api.server.pool.TotalConnections` (gauge): number or total connections
- `daml.index.db.connection.api.server.pool.IdleConnections` (gauge): number of idle connections
- `daml.index.db.connection.api.server.pool.ActiveConnections` (gauge): number of active connections
- `daml.index.db.connection.api.server.pool.PendingConnections` (gauge): number of threads waiting for a connection

`daml.index.db.get_active_contracts`

A database metric. Time spent retrieving a page of active contracts to be served from the active contract service. The page size is configurable, please look at the CLI reference.

`daml.index.db.get_completions`

A database metric. Time spent retrieving a page of command completions to be served from the command completion service. The page size is configurable, please look at the CLI reference.

`daml.index.db.get_flat_transactions`

A database metric. Time spent retrieving a page of flat transactions to be streamed from the transaction service. The page size is configurable, please look at the CLI reference.

`daml.index.db.get_ledger_end`

A database metric. Time spent retrieving the current ledger end. The count for this metric is expected to be very high and always increasing as the indexed is queried for the latest updates.

`daml.index.db.get_ledger_id`

A database metric. Time spent retrieving the ledger identifier.

`daml.index.db.get_transaction_trees`

A database metric. Time spent retrieving a page of flat transactions to be streamed from the transaction service. The page size is configurable, please look at the CLI reference.

`daml.index.db.load_all_parties`

A database metric. Load the currently allocated parties so that they are served via the party management service.

`daml.index.db.load_archive`

A database metric. Time spent loading a package of compiled Daml code so that it's given to the Daml interpreter when needed.

`daml.index.db.load_configuration_entries`

A database metric. Time to load the current entries in the log of configuration entries. Used to verify whether a configuration has been ultimately set.

`daml.index.db.load_package_entries`

A database metric. Time to load the current entries in the log of package uploads. Used to verify whether a package has been ultimately uploaded.

`daml.index.db.load_packages`

A database metric. Load the currently uploaded packages so that they are served via the package management service.

`daml.index.db.load_parties`

A database metric. Load the currently allocated parties so that they are served via the party service.

`daml.index.db.load_party_entries`

A database metric. Time to load the current entries in the log of party allocations. Used to verify whether a party has been ultimately allocated.

`daml.index.db.lookup_active_contract`

A database metric. Time to fetch one contract on the index to be used by the Daml interpreter to evaluate a command into a transaction.

`daml.index.db.lookup_configuration`

A database metric. Time to fetch the configuration so that it's served via the configuration management service.

`daml.index.db.lookup_contract_by_key`

A database metric. Time to lookup one contract key on the index to be used by the Daml interpreter to evaluate a command into a transaction.

`daml.index.db.lookup_flat_transaction_by_id`

A database metric. Time to lookup a single flat transaction by identifier to be served by the transaction service.

`daml.index.db.lookup_maximum_ledger_time`

A database metric. Time spent looking up the ledger effective time of a transaction as the maximum ledger time of all active contracts involved to ensure causal monotonicity.

`daml.index.db.lookup_transaction_tree_by_id`

A database metric. Time to lookup a single transaction tree by identifier to be served by the transaction service.

`daml.index.db.store_configuration_entry`

A database metric. Time spent persisting a change in the ledger configuration provided through the configuration management service.

`daml.index.db.store_ledger_entry`

A database metric. Time spent persisting a transaction that has been successfully interpreted and is final.

`daml.index.db.store_package_entry`

A database metric. Time spent storing a Daml package uploaded through the package management service.

`daml.index.db.store_party_entry`

A database metric. Time spent storing party information as part of the party allocation endpoint provided by the party management service.

`daml.index.db.store_rejection`

A database metric. Time spent persisting the information that a given command has been rejected.

`daml.indexer.last_received_record_time`

A monotonically increasing integer value that represents the record time of the last event ingested by the index db. It is measured in milliseconds since the EPOCH time.

`daml.indexer.last_received_offset`

A string value representing the last ledger offset ingested by the index db. It is only available on metrics backends that support strings. In particular it is not available in Prometheus.

`daml.indexer.current_record_time_lag`

A lag between the record time of a transaction and the wall-clock time registered at the ingestion time to the index db. Depending on the systemic clock skew between different machines, this value can be negative.

`daml.indexer.ledger_end_sequential_id`

A monotonically increasing integer value representing the sequential id ascribed to the most recent ledger event ingested by the index db. Please note, that only a subset of all ledger events are ingested and given a sequential id. These are: creates, consuming exercises, non-consuming exercises and divulgence events. This value can be treated as a counter of all such events visible to a given participant.

`daml.lapi`

Every metrics under this namespace is a timer, one for each service exposed by the Ledger API, in the format:

`daml.lapi.service_name.service_endpoint`

As in the following example:

`daml.lapi.command_service.submit_and_wait`

Single call services return the time to serve the request, streaming services measure the time to return the first response.

`daml.lapi.return_status`

This namespace contains counters for various gRPC return status codes in the following format

`daml.lapi.return_status.<gRPC status code>`

As in the following example:

`daml.lapi.return_status.ABORTED`

`daml.services`

Every metrics under this namespace is a timer, one for each endpoint exposed by the index, read or write service. Metrics are in the format:

```
daml.services.service_name.service_endpoint
```

The following example demonstrates a metric for transactions submitted over the write service:

```
daml.services.write.submit_transaction
```

Single call services return the time to serve the request, streaming services measure the time to return the first response.

`jvm`

Under the `jvm` namespace there is a collection of metrics that tracks important measurements about the JVM that the sandbox is running on, including CPU usage, memory consumption and the current state of threads.

15.8 Visualize: Daml Navigator (Deprecated)

Warning: Since Daml 2.9.0, `daml navigator` is deprecated. It will be removed in Daml 3.0.

The Navigator is a front-end that you can use to connect to any Daml Ledger and inspect and modify the ledger. You can use it during Daml development to explore the flow and implications of the Daml models.

The first sections of this guide cover use of the Navigator with the SDK. Refer to [Advanced Usage](#) for information on using Navigator outside the context of the SDK.

15.8.1 Navigator Functionality

Connect the Navigator to any Daml Ledger and use it to:

- View templates
- View active and archived contracts
- Exercise choices on contracts
- Advance time (This option applies only when using Navigator with the Daml Sandbox ledger.)

15.8.2 Starting Navigator

Navigator is included in the SDK. To launch it:

1. Start Navigator via a terminal window running [Daml Assistant](#) by typing `daml start`
2. The Navigator web-app is automatically started in your browser. If it fails to start, open a browser window and point it to the Navigator URL

When running `daml start` you will see the Navigator URL. By default it will be <http://localhost:7500/>.

Note: Navigator is compatible with these browsers: Safari, Chrome, or Firefox.

15.8.3 Logging In

By default, Navigator shows a drop-down list with the users that have been created via the [user management service](#). During development, it is common to create these users in a [Daml script](#): that you specify in the `init-script` section of your `daml.yaml` file so it is executed on `daml start`. Most of the templates shipped with the Daml SDK already include such a setup script. Only users that have a primary party set will be displayed.

After logging in, you will interact with the ledger as the primary party of that user, meaning that you can see contracts visible to that party and submit commands (e.g. create a contract) as that party.

The party you are logged in as is not displayed directly. However, Navigator provides autocompletion based on the party id which starts with the party id hint so a good option is to set the party id hint to the user id when you allocate the party in your setup script. You can see an example of that in the skeleton template:

```
alice <- allocatePartyWithHint "Alice" (PartyIdHint "Alice")
bob <- allocatePartyWithHint "Bob" (PartyIdHint "Bob")
aliceId <- validateUserId "alice"
bobId <- validateUserId "bob"
createUser (User aliceId (Some alice)) [CanActAs alice]
createUser (User bobId (Some bob)) [CanActAs bob]
```

The first step in using Navigator is to use the dropdown list on the Navigator home screen to select from the available users.

The main Navigator screen will be displayed, with contracts that the primary party of this user is entitled to view in the main pane and the option to switch from contracts to templates in the pane at the left. Other options allow you to filter the display, include or exclude archived contracts, and exercise choices as described below.

To change the active user:

1. Click the name of the current user in the top left corner of the screen.
2. On the home screen, select a different user.

You can act as different users in different browser windows. Use Chrome's profile feature <https://support.google.com/chrome/answer/2364824> and sign in as a different user for each Chrome profile.

15.8.3.1 Logging in as a Party

Instead of logging in by specifying a user, you can also log in by specifying a party directly. This is useful if you do not want to or cannot (because your ledger does not support user management) create users.

To do so, you can start Navigator with a flag to disable support for user management:

```
daml navigator --feature-user-management=false
```

To use this via `daml start`, you can specify it in your `daml.yaml` file:

```
navigator-options:
  - --feature-user-management=false
```

Instead of displaying a list of users on login, Navigator will display a list of parties where each party is identified by its display name.

Alternatively you can specify a fixed list of parties in your `daml.yaml` file. This will automatically disable user management and display those parties on log in. Note that you still need to allocate those parties before you can log in as them.

parties:

- Alice::12201d00faa0968d7ab81e63ad6ad4ee0d31b08a3581b1d8596e68a1356f27519ccb
- Bob::12201d00faa0968d7ab81e63ad6ad4ee0d31b08a3581b1d8596e68a1356f27519ccb

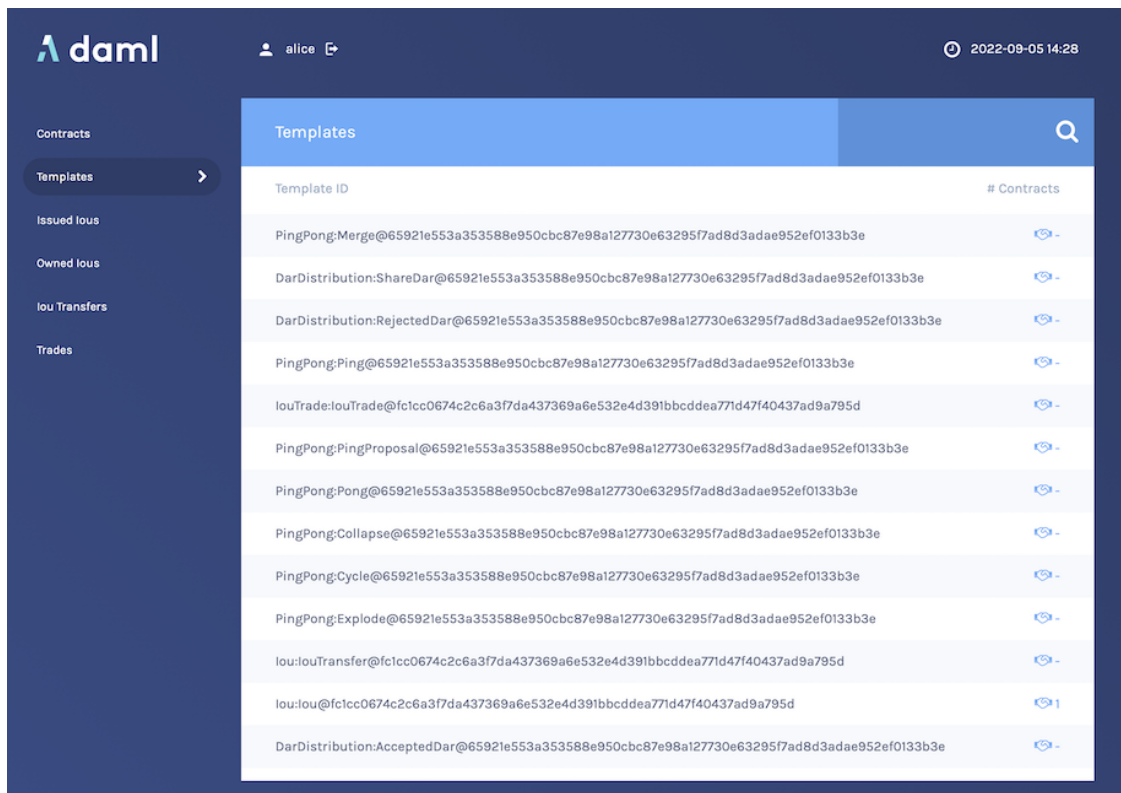

15.8.4 Viewing Templates or Contracts

Daml *contract templates* are models that contain the agreement statement, all the applicable parameters, and the choices that can be made in acting on that data. They specify acceptable input and the resulting output. A contract template contains placeholders rather than actual names, amounts, dates, and so on. In a contract, the placeholders have been replaced with actual data.

The Navigator allows you to list templates or contracts, view contracts based on a template, and view template and contract details.

15.8.4.1 Listing templates

To see what contract templates are available on the ledger you are connected to, choose **Templates** in the left pane of the main Navigator screen.

Template ID	# Contracts
PingPong:Merge@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
DarDistribution:ShareDar@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
DarDistribution:RejectedDar@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
PingPong:Ping@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
louTrade:louTrade@fc1cc0674c2c6a3f7da437369a6e532e4d391bbcddea771d47f40437ad9a795d	0
PingPong:PingProposal@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
PingPong:Pong@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
PingPong:Collapse@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
PingPong:Cycle@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
PingPong:Explode@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0
lou:louTransfer@fc1cc0674c2c6a3f7da437369a6e532e4d391bbcddea771d47f40437ad9a795d	0
lou:lou@fc1cc0674c2c6a3f7da437369a6e532e4d391bbcddea771d47f40437ad9a795d	1
DarDistribution:AcceptedDar@65921e553a353588e950cbc87e98a127730e63295f7ad8d3adae952ef0133b3e	0

Use the **Filter** field at the top right to select template IDs that include the text you enter.

15.8.4.2 Listing contracts

To view a list of available contracts, choose **Contracts** in the left pane.

In the Contracts list:

Changes to the ledger are automatically reflected in the list of contracts. To avoid the automatic updates, select the **Frozen** checkbox. Contracts will still be marked as archived, but the contracts list will not change.

Filter the displayed contracts by entering text in the **Filter** field at the top right. Use the **Include Archived** checkbox at the top to include or exclude archived contracts.

15.8.4.3 Viewing contracts based on a template

You can also view the list of contracts that are based on a particular template.

1. You will see icons to the right of template IDs in the template list with a number indicating how many contracts are based on this template.
2. Click the number to display a list of contracts based on that template.

Number of Contracts

The screenshot shows the Daml Navigator interface with the 'Templates' view selected. The table lists various contract templates, including 'PingPong:Merge', 'DarDistribution:ShareDar', 'DarDistribution:RejectedDar', 'PingPong:Ping', 'louTrade:louTrade', 'PingPong:PingProposal', 'PingPong:Pong', 'PingPong:Collapse', 'PingPong:Cycle', 'PingPong:Explode', 'lou:louTransfer', 'lou:lou', and 'DarDistribution:AcceptedDar'. The 'lou:louTransfer' template is highlighted with a red circle, and its corresponding blue eye icon is also circled in red.

List of Contracts

The screenshot shows the Daml Navigator interface with the 'Contracts for [lou:lou@fc1cc0674c2c6a3f7...]' view selected. The table displays contract details for a specific issuer. The table has columns for ID, issuer, owner, currency, amount, observers, and Choice.

ID	issuer	owner	currency	amount	observers	Choice
0044...	"EUR_Bank::1220..."	"Alice::122089e95..."	"EUR"	"100.0"	[]	

15.8.4.4 Viewing template and contract details

To view template or contract details, click on a template or contract in the list. The template or contracts detail page is displayed.

Template Details

The screenshot shows the Daml SDK interface for viewing a template. The left sidebar contains a navigation menu with the following items: Contracts, Templates, Issued Iou, Owned Iou, Iou Transfers, and Trades. The main content area displays the details for a template with ID `Template Iou:Iou@fc1cc0674c2c6a3f7da437369a6e532e4d391bbcddea771d47f40437ad9a795d`. The details are organized into sections: **issuer** (Party), **owner** (Party), **currency** (Text), **amount** (Numeric 10), and **observers**. Below the observers section, there are two buttons: "Add new element" and "Delete last element". At the bottom of the form is a large blue "Submit" button. The top of the interface shows the user "alice" and the timestamp "2022-09-05 14:36".

Contract Details

The screenshot shows the Daml SDK interface for viewing a contract. The left sidebar is the same as in the previous screenshot. The main content area displays the details for a contract with ID `Contract 0044f8af99d0...`. At the top of the contract details, there are several action buttons: "Iou_AddObserver", "Iou_Split", "Iou_RemoveObserver", "Iou_Transfer", "Iou_Merge", and "Archive". Below these buttons, the template ID is shown: `Iou:Iou@fc1cc0674c2c6a3f7da437369a6e532e4d391bbcddea771d47f40437ad9a795d`. The contract details are organized into sections: **Signatories** (listing `Alice::122089e95343...` and `EUR_Bank::122089e95343...`), **Contract details** (listing **issuer** as `EUR_Bank::122089e95343...`, **owner** as `Alice::122089e95343...`, **currency** as EUR, **amount** as 100.0, and **observers** as (empty list)). The top of the interface shows the user "alice" and the timestamp "2022-09-05 14:36".

15.8.5 Using Navigator

15.8.5.1 Creating contracts

Contracts in a ledger are created automatically when you exercise choices. In some cases, you create a contract directly from a template. This feature can be particularly useful for testing and experimenting during development.

To create a contract based on a template:

1. Navigate to the template detail page as described above.
2. Complete the values in the form
3. Choose the **Submit** button.

When the command has been committed to the ledger, the loading indicator in the navbar at the top will display a tick mark.

While loading

When committed to the ledger

15.8.5.2 Exercising choices

To exercise a choice:

1. Navigate to the contract details page (see above).
2. Click the choice you want to exercise in the choice list.
3. Complete the form.
4. Choose the **Submit** button.

Or

1. Navigate to the choice form by clicking the wrench icon in a contract list.
2. Select a choice.

You will see the loading and confirmation indicators, as pictured above in Creating Contracts.

15.8.5.3 Advancing time

It is possible to advance time against the Daml Sandbox. (This is not true of all Daml Ledgers.) This advance-time functionality can be useful when testing, for example, when entering a trade on one date and settling it on a later date.

To advance time:

1. Click on the ledger time indicator in the navbar at the top of the screen.
2. Select a new date / time.
3. Choose the **Set** button.

15.8.6 Authorizing Navigator

If you are running Navigator against a Ledger API server that verifies authorization, you must provide the access token when you start the Navigator server.

The access token retrieval depends on the specific Daml setup you are working with: please refer to the ledger operator to learn how.

Once you have retrieved your access token, you can provide it to Navigator by storing it in a file and provide the path to it using the `--access-token-file` command line option.

If the access token cannot be retrieved, is missing or wrong, you'll be unable to move past the Navigator's frontend login screen and see the following:

15.8.7 Advanced Usage

15.8.7.1 Customizable table views

Customizable table views is an advanced rapid-prototyping feature, intended for Daml developers who wish to customize the Navigator UI without developing a custom application.

To use customized table views:

1. Create a file `frontend-config.js` in your project root folder (or the folder from which you run Navigator) with the content below:

```
import { DamlLfValue } from '@da/ui-core';

export const version = {
  schema: 'navigator-config',
  major: 2,
  minor: 0,
};

export const customViews = (userId, party, role) => ({
  customview1: {
    type: "table-view",
    title: "Filtered contracts",
    source: {
      type: "contracts",
      filter: [
        {
          field: "id",
          value: "1",
        }
      ],
      search: "",
      sort: [
        {
          field: "id",
          direction: "ASCENDING"
        }
      ]
    },
    columns: [
      {
        key: "id",
        title: "Contract ID",
        createCell: ({rowData}) => ({
          type: "text",
          value: rowData.id
        }),
        sortable: true,
        width: 80,
        weight: 0,
        alignment: "left"
      },
      {
        key: "template.id",
        title: "Template ID",
        createCell: ({rowData}) => ({
```

(continues on next page)

(continued from previous page)

```

        type: "text",
        value: rowData.template.id
    }},
    sortable: true,
    width: 200,
    weight: 3,
    alignment: "left"
  }
]
}
})

```

2. Reload your Navigator browser tab. You should now see a sidebar item titled `Filtered contracts` that links to a table with contracts filtered and sorted by ID.

To debug config file errors and learn more about the config file API, open the Navigator `/config` page in your browser (e.g., <http://localhost:7500/config>).

15.8.7.2 Using Navigator with a Daml Ledger

By default, Navigator is configured to use an unencrypted connection to the ledger. To run Navigator against a secured Daml Ledger, configure TLS certificates using the `--pem`, `--crt`, and `--cacrt` command line parameters. Details of these parameters are explained in the command line help:

```
daml navigator --help
```

15.9 Measure: Daml Profiler

The Daml Profiler is only available in [Daml Enterprise](#).

The Daml Profiler allows you to profile execution of your Daml code which can help spot bottlenecks and opportunities for optimization.

15.9.1 Usage

To test this out, we use the skeleton project included in the assistant. We first create the project and build the DAR.

```

daml new profile-tutorial --template skeleton
cd profile-tutorial
daml build

```

Next we load the DAR into Sandbox with a special `profile-dir` option. Sandbox will behave as usual but all profile results will be written to that directory. For this, we first create a configuration file that sets the `profile-dir` for Sandbox:

Listing 4: profile.conf

```
canton.participants.sandbox.features.profile-dir = profile-results
```

We then pass

```
daml sandbox --dar .daml/dist/profile-tutorial-0.0.1.dar -c profile.conf
```

To actually produce some profile results, we have to create transactions. For the purposes of this tutorial, the Daml Script included in the skeleton project does the job admirably:

```
daml script --dar .daml/dist/profile-tutorial-0.0.1.dar --ledger-host localhost --  
↪ledger-port 6865 --script-name Main:setup
```

If we now look at the contents of the `profile-results` directory, we can see one JSON file per transaction produced by the script. Each file has a name of the form `$timestamp-$command.json` where `$timestamp` is the submission time of the transaction and `$command` is a human-readable description of the command that produced the transaction (for multi-command submissions, only the first one will be in the file name).

```
$ ls profile-results  
2021-03-17T12:32:16.846404Z-create:Asset.json  
2021-03-17T12:32:17.361596Z-exercise:Asset:Give.json  
2021-03-17T12:32:17.623537Z-exercise:Asset:Give.json
```

At this point, you can stop Sandbox.

To view the profiling results you can use [speedscope](#). The easiest option is to use the [web version](#) but you can also install it [locally](#).

Let's open the first exercise profile above `2021-03-17T12:32:17.361596Z-exercise:Asset:Give.json`:

You can see the exercise as the root of the profile. Below that there are a few expressions to calculate signatories, observer and controllers and finally we see the create of the contract. In this simple example, nothing obvious stands out that we could do to optimize further.

Speedscope provides a few other views that can be useful depending on your profile. Refer to the [documentation](#) for more information on that.

15.9.2 Caveats

1. The profiler currently does not take time into account that is spent outside of pure interpretation, e.g., time needed to fetch a contract from the database.
2. The profiler operates on Daml-LF. This means that the identifiers used in the profiler correspond to Daml-LF expressions which includes autogenerated identifiers used by the compiler. E.g., in the example above, `Main:$csignatory` is the name of the function used to compute signatories of `Asset`. You can view the Daml-LF code that the compiler generated using `daml damlc inspect`. This can be useful to see where an identifier is being used but it does take some experience to be able to read Daml-LF code with ease.

```
daml damlc inspect .daml/dist/profiler-tutorial-0.0.1.dar
```

15.10 Daml Codegen

15.10.1 Introduction

You can use the Daml codegen to generate Java, and JavaScript/TypeScript classes representing Daml contract templates. These classes incorporate all boilerplate code for constructing corresponding ledger `com.daml.ledger.api.v1.CreateCommand`, `com.daml.ledger.api.v1.ExerciseCommand`, `com.daml.ledger.api.v1.ExerciseByKeyCommand`, and `com.daml.ledger.api.v1.CreateAndExerciseCommand`.

15.10.2 Run the Daml Codegen

The basic command to run the Daml codegen is:

```
$ daml codegen [java|js] [options]
```

There are two modes:

Command line configuration, specifying **all** settings in the command line (all codegens supported)

Project file configuration, specifying **all** settings in the `daml.yaml` (currently **Java** only)

15.10.2.1 Command Line Configuration

Help for each specific codegen:

```
$ daml codegen [java|js] --help
```

Java codegens take the same set of configuration settings:

```
<DAR-file[=package-prefix]>...
    DAR file to use as input of the codegen with an optional,
    ↪ but recommend, package prefix for the generated sources.
-o, --output-directory <value>
    Output directory for the generated sources
-d, --decoderClass <value>
```

(continues on next page)

(continued from previous page)

```

    Fully Qualified Class Name of the optional Decoder
  ↪utility
-V, --verbosity <value> Verbosity between 0 (only show errors) and 4 (show all
  ↪messages) -- defaults to 0
-r, --root <value> Regular expression for fully-qualified names of
  ↪templates to generate -- defaults to .*
--help This help text

```

JavaScript/TypeScript codegen takes a different set of configuration settings:

```

DAR-FILES DAR files to generate TypeScript bindings for
-o DIR Output directory for the generated packages
-s SCOPE The NPM scope name for the generated packages;
defaults to daml.js
-h, --help Show this help text

```

15.10.2.2 Project File Configuration (Java)

The above settings can be configured in the `codegen` element of the Daml project file `daml.yaml`. See [this issue](#) for status on this feature.

Here is an example:

```

sdk-version: 2.0.0
name: quickstart
source: daml
init-script: Main:initialize
parties:
  - Alice
  - Bob
  - USD_Bank
  - EUR_Bank
version: 0.0.1
exposed-modules:
  - Main
dependencies:
  - daml-prim
  - daml-stdlib
codegen:
  js:
    output-directory: ui/daml.js
    npm-scope: daml.js
  java:
    package-prefix: com.daml.quickstart.iou
    output-directory: java-codegen/src/main/java
    verbosity: 2

```

You can then run the above configuration to generate your **Java** code:

```
$ daml codegen java
```

The equivalent **JavaScript** command line configuration would be:

```
$ daml codegen js ../daml/dist/quickstart-0.0.1.dar -o ui/daml.js -s daml.js
```

and the equivalent **Java** command line configuration:

```
$ daml codegen java ../daml/dist/quickstart-0.0.1.dar=com.daml.quickstart.iou --  
↪output-directory=java-codegen/src/main/java --verbosity=2
```

In order to compile the resulting **Java** classes, you need to add the corresponding dependencies to your build tools.

For **Java**, add the following **Maven** dependency:

```
<dependency>  
  <groupId>com.daml</groupId>  
  <artifactId>bindings-java</artifactId>  
  <version>YOUR_SDK_VERSION</version>  
</dependency>
```

Note: Replace `YOUR_SDK_VERSION` with the version of your SDK

Chapter 16

Daml Finance Documentation

Welcome to the Daml Finance documentation. This page provides an overview of the documentation content as well as suggested starting points. Use the left-hand menu to explore the various sections, or the search bar above for quick navigation. If you are missing content from the documentation, have feedback on the library, or need any help using it, do not hesitate to [open an issue](#) on the repository.

16.1 Content

Overview: description of the purpose of the library, its high-level architecture, as well as targeted use cases

Concepts: explanation of the main concepts used throughout the library, and how they fit together

Instruments: description of the instruments that are included in Daml Finance and can be used out of the box

Packages: documentation for each individual package and its contained modules

Tutorials: step-by-step implementation guides across different use cases

Reference: glossary as well as code-level documentation for each package

16.2 Starting Points

The following is a suggested learning path to get productive quickly:

1. [Get started](#) quickly
2. Read up on the [background, purpose, and intended usage](#) of the library
3. Understand the [fundamental concepts](#) in depth
4. Learn how to [use the instrument packages to model different financial instruments](#)
5. Explore the [Daml Finance Demo Application](#)
6. Ask questions in the [Forum](#) or read existing discussions

16.3 Packages

16.3.1 How to Download

Daml Finance is distributed as a set of packages. There are two main ways how to download Daml Finance:

New users are recommended to follow the [Getting started](#) tutorial, which also contains a `get-dependencies` script that downloads the Daml Finance packages. This allows you to learn Daml Finance at the same time.

Advanced users can download Daml Finance directly from the [Releases section of the repo](#), either the individual packages that your application needs or a bundle containing all packages.

16.3.2 Current Release

Daml SDK 2.10.0

This section details the list of released and deprecated packages, with status information provided for each package according to the [Daml Ecosystem convention](#). Additionally, a section is included to highlight and explain the major updates and enhancements introduced since the last release.

Important Note: The current Daml Finance release was built with Daml SDK 2.10.0 and Daml LF version 1.17 (LF 1.17) to enable Smart Contract Upgrading (SCU). To use this release, ensure your project is using Daml SDK 2.10.0 or later and LF 1.17. By default, SDK 2.10.0 uses LF 1.15, but you can enable LF 1.17 by adding `-target=1.17` as *build-options* in your `daml.yaml` file.

16.3.2.1 Smart Contract Upgradeability

Daml Finance is now SCU compatible by relying on Daml SDK 2.10.0 and Daml LF 1.17. As part of this change, each package incorporates its major version number (Vx) into its path, package name, and module name. Consequently, the major version for all Daml Finance packages has been incremented.

16.3.2.2 Context-Aware Semaphore Lock Release

A fix added to the `Daml.Finance.Util` package ensures that a holding protected by a semaphore lock will only be released if the lock's context matches the provided unlock context. This prevents inadvertent releases.

16.3.2.3 New AutoCallable Instrument

A new AutoCallable instrument [AutoCallable](#) has been added to the experimental `Daml.Finance.Instrument.StructuredProduct.V0` package. This addition expands the set of available structured product instruments.

Stable Packages

Package	Version	Status
ContingentClaims.Core.V3	3.0.0	Stable
ContingentClaims.Lifecycle.V3	3.0.0	Stable
Daml.Finance.Account.V4	4.0.0	Stable
Daml.Finance.Claims.V3	3.0.0	Stable
Daml.Finance.Data.V4	4.0.0	Stable
Daml.Finance.Holding.V4	4.0.0	Stable
Daml.Finance.Instrument.Bond.V3	3.0.0	Stable
Daml.Finance.Instrument.Generic.V4	4.0.0	Stable
Daml.Finance.Instrument.Token.V4	4.0.0	Stable
Daml.Finance.Interface.Account.V4	4.0.0	Stable
Daml.Finance.Interface.Claims.V4	4.0.0	Stable
Daml.Finance.Interface.Data.V4	4.0.0	Stable
Daml.Finance.Interface.Holding.V4	4.0.0	Stable
Daml.Finance.Interface.Instrument.Base.V4	4.0.0	Stable
Daml.Finance.Interface.Instrument.Bond.V3	3.0.0	Stable
Daml.Finance.Interface.Instrument.Generic.V4	4.0.0	Stable
Daml.Finance.Interface.Instrument.Token.V4	4.0.0	Stable
Daml.Finance.Interface.Instrument.Types.V2	2.0.0	Stable
Daml.Finance.Interface.Lifecycle.V4	4.0.0	Stable
Daml.Finance.Interface.Settlement.V4	4.0.0	Stable
Daml.Finance.Interface.Types.Common.V3	3.0.0	Stable
Daml.Finance.Interface.Types.Date.V3	3.0.0	Stable
Daml.Finance.Interface.Util.V3	3.0.0	Stable
Daml.Finance.Lifecycle.V4	4.0.0	Stable
Daml.Finance.Settlement.V4	4.0.0	Stable
Daml.Finance.Util.V4	4.0.0	Stable

Early Access Packages

Package	Version	Status
ContingentClaims.Valuation.V0	0.3.0	Labs
Daml.Finance.Instrument.Equity.V0	0.5.0	Alpha
Daml.Finance.Instrument.Option.V0	0.4.0	Alpha
Daml.Finance.Instrument.StructuredProduct.V0	0.2.0	Alpha
Daml.Finance.Instrument.Swap.V0	0.5.0	Alpha
Daml.Finance.Interface.Instrument.Equity.V0	0.5.0	Alpha
Daml.Finance.Interface.Instrument.Option.V0	0.4.0	Alpha
Daml.Finance.Interface.Instrument.StructuredProduct.V0	0.2.0	Alpha
Daml.Finance.Interface.Instrument.Swap.V0	0.5.0	Alpha

Chapter 17

Overview

This overview section describes the purpose of the Daml Finance library, its high-level architecture, as well as targeted use cases.

17.1 Introduction

17.1.1 Purpose

Daml Finance supports the modeling of financial and non-financial use cases in Daml. It provides a standard way to represent assets on Daml ledgers and defines common behaviours and rules. There are two main benefits to using the library in your application:

Shortened time-to-market

Implementing basic financial concepts like ownership or economic terms of an asset is a complex and tedious task. By providing common building blocks, Daml Finance increases delivery velocity and shortens the time-to-market when building Daml applications. The rich set of functionality of Daml Finance is at your disposal so you don't have to reinvent the wheel.

Application composability

Building your application on Daml Finance makes it compatible with other platforms in the wider ecosystem. By using a shared library assets become *mobile*, allowing them to be used seamlessly across application boundaries without the need for translation or integration layers. For instance, a Daml Finance-based asset that is originated in a bond issuance application can be used in the context of a secondary market trading application that is also built on Daml Finance.

17.1.2 Design Goals

Daml Finance optimizes for the following aspects:

Accessibility

The library is designed to have a low barrier to entry. Users familiar with Daml can get started quickly and leverage the provided functionality easily.

Maintainability

Building with Daml Finance decouples your application code from the underlying representation of assets. This allows the application to evolve without the need to migrate assets from one version to another, and makes maintenance easier.

Extensibility

Various extension points allow customization and extension of the library as required. If an existing implementation does not fulfill the requirements it is straightforward to provide a custom extension.

17.1.3 Scope

The library covers the following areas:

Holdings: modeling of ownership structures, custodial relationships, intermediated securities, and accounts

Instruments: structuring the economic terms of an asset and the events that govern its evolution

Settlement: executing complex transactions involving multiple parties and assets

Lifecycle: governing the evolution of financial instruments over their lifetime

17.1.4 Use Cases

Daml Finance comes with broad asset and workflow capabilities to allow for a variety of use cases to be modeled:

Simple tokens: digital representation of traditional assets

Central bank digital currency: retail or wholesale distribution models

Standard asset classes: equities with corporate actions, bonds with flexible cash flow modeling

Derivatives: time- and path-dependent derivatives with optionality

Synchronized lifecycle: atomic, intermediated lifecycle and settlement of cash flows across investors and custodians

Cross-entity issuance: atomic, multi-party issuance across investors, issuer, risk book, and treasury

Asset-agnostic trading facility: generic delivery-vs-payment and immediate, guaranteed settlement

Exotic asset types: non-fungible and non-transferable assets

17.1.5 Exploring the Library

If you want to review the Daml Finance codebase in more detail you can clone [the repository](#) locally on your machine. This allows you to navigate the code, including both the template definitions and the tests. In particular the tests are useful to show how the library works and how the different components interact with each other. If you need to view the code for a specific package release, you can check out the [corresponding tag](#).

As a pre-requisite, the [Daml SDK](#) needs to be installed on your machine.

In order to download the repository, open a terminal and run:

```
git clone git@github.com:digital-asset/daml-finance.git
```

This creates a new folder `daml-finance` containing the Daml Finance source code. Navigate to the folder and run:

```
make build
```

This downloads all required packages and builds the project. You can then run:

```
daml studio
```

to open the code editor and inspect the code.

17.1.6 Demo Application

In addition to Daml Finance, there is also a separate Demo Application, showcasing several of the library's capabilities in a web-based graphical user interface.

If you are interested in trying out the app locally, you can clone the corresponding repo and follow the installation instructions on the [Daml Finance Demo App GitHub page](#).

17.2 Architecture

This page outlines the architecture of the library and the relationships between the different packages.

Daml Finance consists of a set of `.dar` packages that can be divided into two layers:

- an *interface layer* representing its public, stable API
- an *implementation layer* providing a set of default implementation packages

17.2.1 Interface Layer

The interface layer provides common types and Daml interface definitions that represent the public API of Daml Finance. It includes several Daml packages, each grouping related business functions. These packages can in principle be used independently of each other.

The interface layer consists of the following packages:

- `Daml.Finance.Interface.Holding.V4` defines interfaces for holdings and related properties such as [transferability](#) or [fungibility](#).
- `Daml.Finance.Interface.Account.V4` defines interfaces for accounts
- `Daml.Finance.Interface.Settlement.V4` defines interfaces for settlement route providers, settlement instructions, and batched settlements
- `Daml.Finance.Interface.Lifecycle.V4` defines interfaces used for instrument lifecycle
- `Daml.Finance.Interface.Instrument.*` contains interfaces used for different instrument types
- `Daml.Finance.Interface.Claims.V4` contains interfaces used for [Contingent Claims](#) based instrument types
- `Daml.Finance.Interface.Data.V4` defines interfaces related to reference data
- `Daml.Finance.Interface.Types.Common.V3` provides common types
- `Daml.Finance.Interface.Types.Date.V3` provides types related to dates

`Daml.Finance.Interface.Util.V3` defines utilities and interfaces used by other interface packages.

`ContingentClaims.Core.V3` contains types for representing [Contingent Claims](#) tree structures.

17.2.2 Implementation Layer

The implementation layer contains concrete template definitions implementing the interfaces defined in the interface layer. These represent the contracts that are ultimately stored on the ledger.

For instance, `Daml.Finance.Holding.V4` contains a concrete implementation of a [Transferable](#) and [Fungible](#) holding. These interfaces are defined in `Daml.Finance.Interface.Holding.V4`.

The implementation layer consists of the following packages:

`Daml.Finance.Holding.V4` defines default implementations for holdings

`Daml.Finance.Account.V4` defines default implementations for accounts

`Daml.Finance.Settlement.V4` defines templates for settlement route providers, settlement instructions, and batched settlements

`Daml.Finance.Lifecycle.V4` defines an implementation of lifecycle effects and a rule template to facilitate their settlement

`Daml.Finance.Instrument.*` contains implementations for various instrument types

`Daml.Finance.Data.V4` includes templates used to store reference data on the ledger

`Daml.Finance.Claims.V3` contains utility functions relating to [Contingent Claims](#) based instruments and lifecycling

`Daml.Finance.Util.V4` provides a set of pure utility functions mainly for date manipulation

`ContingentClaims.Lifecycle.V3` provides lifecycle utility functions for [Contingent Claims](#) based instruments

`ContingentClaims.Valuation.V0` contains experimental functions to transform [Contingent Claims](#) instrument trees into a mathematical representation suitable for integration with pricing and risk frameworks

17.2.3 Versioning and Compatibility

Daml Finance follows the semantic versioning scheme.

The interface packages define the public API of the library. Specifically, the interface definitions which include interface views, methods and choices are guaranteed to remain stable within a major version of a package. Note that this does not include the package id itself. So purely additive (e.g. adding new interfaces), or non-functional changes (like compiling a package with a later SDK version), which do change the package id of a package but do not change the interface definitions, can be released in minor or patch version increments. Such changes will require dependent applications to be recompiled and upgraded, but the upgrades are trivial as none of the existing interfaces changed functionally.

Implementation packages follow a similar convention. A purely additive change, or a change that does not affect the implemented interfaces can be rolled out as a minor or patch version increase. Similarly, an upgrade to implement a new *minor* or *patch* version of of an interface, which doesn't functionally change the interface implementation is also considered a minor or patch version increase of an implementation package. If an implementation package changes to implement a new major version of an interface the major version of the implementation will change as well.

We intend to document the upgrade process and/or provide sample upgrade scripts for contracts within the Daml Finance perimeter for major version upgrades only.

Note that deprecations of package versions only happen in the context of a Daml SDK release. They will be listed in the [release section](#) of the documentation and follow the standard Daml component [deprecation guidelines](#).

17.3 Building Applications

This page describes the patterns to follow when building applications using Daml Finance.

17.3.1 Installing Daml Finance

Each Daml SDK release defines a set of consistent Daml Finance package versions that have been tested to work with each other. The list of package versions for each Daml SDK release can be found [here](#). To facilitate getting started with a particular release set, the Daml SDK comes with a `quickstart-finance` template that contains a script to download these packages.

After installing the Daml SDK, you can execute the following commands to create a new Daml Finance project based on the set of packages released with the given SDK version:

On Unix-based systems execute:

```
daml new quickstart-finance --template=quickstart-finance
cd quickstart-finance
./get-dependencies.sh
```

On Windows-based systems execute:

```
daml new quickstart-finance --template=quickstart-finance
cd quickstart-finance
get-dependencies.bat
```

You can then edit the `daml.yaml` file and uncomment the lines corresponding to the packages you require in your project.

Alternatively, if you want to install the latest Daml Finance version into an existing project, you can copy and execute these scripts ([Unix](#) and [Windows](#) variants) from the main branch of the repository.

17.3.2 Application Architecture

When building applications using Daml Finance it is important to ensure your application only depends on the interface layer (i.e., the public API) of Daml Finance. Furthermore, it is suggested that your application follows a similar split between interface (API) and implementation layer in order to maximize upgradability and minimize the impact of incremental changes to your application or Daml Finance.

The following picture shows a suggested architecture that minimizes undesirable coupling and optimizes for upgradability of your application:

The following annotations are highlighted in the diagram:

1. The customer application should be split into an implementation and an interface (API) layer. This ensures that implementations can be upgraded without affecting client-side applications, like the UI, integrations, or Daml Triggers [\(deprecated\)](#).
2. The customer application (both the interface and implementation layer) should only depend on the interface layer (API) of Daml Finance. This ensures that upgrades to the implementation layer of Daml Finance do not affect the Customer Application.
3. All client-side code (UI, integrations, Daml Triggers, etc.) should only depend on the interface layers of Daml Finance and the Customer Application. This ensures that any implementation upgrades in Daml Finance or the Customer Application do not affect client-side code.
4. Any setup scripts used to initialize the application can (and usually have to) depend on the implementation layers of Daml Finance and the Customer Application. This is required to set

up contracts like factories, where a dependency on the implementation package is needed. It does not affect the overall upgradability of the Customer Application as these operations are usually executed either at initial setup or on a one-off basis, but not during normal operation of the application.

Following the above patterns ensures minimal impact of changes to any implementation part of the overall application:

If a Daml Finance implementation package is upgraded, only the contracts for templates within the package have to be upgraded. The Customer Application itself is unaffected because it only depends on the interface packages, which remain unchanged.

If a customer application implementation package is upgraded, only the contracts for templates within that package need to be upgraded. The client-side code of the application is unaffected, as it only depends on the Customer Application interface layer.

If a Daml Finance interface package is upgraded, the affected parts in the customer application implementation, interface, or client-side layer need to be upgraded. To minimize the impact of such change it is suggested that the customer application layers themselves are divided into packages, that each depend on a minimal set of Daml Finance interface packages.

If a customer application interface package is upgraded the corresponding implementation packages, as well as the affected client-side code have to be upgraded. Again, splitting up the interface (API) layer of the customer application can minimize the impact of such a change.

In general, we will provide upgrade contracts and scripts to facilitate migration between major version updates of packages within the Daml Finance perimeter.

17.3.3 Using Daml Codegen

The Daml Finance packages are compatible with the [Daml Codegen tool](#).

If you, e.g., want to create a JavaScript app that uses Daml Finance, it is possible to generate JavaScript classes from the Daml Finance packages you need. Use [daml codegen js](#), for example:

```
daml codegen js -o ./output .lib/daml-finance-interface-instrument-swap-0.2.1.dar  
↪.lib/daml-finance-interface-instrument-bond-0.2.1.dar
```

Alternatively, if your app uses Java, you can run [daml codegen java](#) in a similar way:

```
daml codegen java -o ./output .lib/daml-finance-interface-instrument-swap-0.2.1.  
↪dar .lib/daml-finance-interface-instrument-bond-0.2.1.dar
```

Note, this Daml Finance codegen is only supported on SDK versions 2.5.x and higher.

17.4 Extending Daml Finance

Daml Finance is designed to be extended whenever the provided implementations do not satisfy the requirements at hand. In principle, all interfaces in the [interface layer](#) can be implemented with custom implementations. Specific extension points we expect and encourage users to customize are explained below.

Note that for all of the listed extension points, we are happy to receive external contributions to be included in the library.

17.4.1 Custom Holding Implementations

Daml Finance provides default holding implementations for the following holding standards:

1. fungible only (i.e., the *Fungible* holding standard)
2. transferable only (i.e., *Transferable* holding standard)
3. both transferable and fungible (i.e., the *TransferableFungible* holding standard)
4. neither fungible nor transferable (i.e., the *BaseHolding* holding standard)

The transferability of transferable holdings can be flexibly controlled through the [controllers](#) property on an [Account](#). Some use cases, however, might require additional functionality on holding contracts:

Restricted transferability: a custom implementation of the [Transferable interface](#) can enforce additional conditions (e.g. the presence of some contract) required to transfer a holding.

Fixed divisibility: a custom implementation of the [Fungible interface](#) can enforce specific requirements regarding the divisibility of a holding.

Additional information: a custom implementation of a holding can provide additional information, for example, the timestamp of when the holding was obtained. This can be used to implement features that depend on the time a particular asset has been held (e.g. holding fees, interest, etc.).

Note that any custom holding implementation will still allow you to leverage other parts of the library (e.g. lifecycling or settlement) as those are implemented against the respective interfaces. You will need to provide an implementation of the [Holding Factory](#) interface for your implementation to be usable throughout the library.

17.4.2 Custom Account Implementations

The default account implementation in Daml Finance allows you to define authorization requirements for incoming and outgoing transfers through the [controllers](#) property. For some cases, however, a custom account implementation may be warranted:

Restricted credit and debit: a custom implementation of the `Credit` and / or `Debit` choices on the [Account interface](#) can place additional restrictions on those actions that can depend, for example, on the presence of a separate know-your-customer (KYC) contract.

Additional information: a custom account implementation can serve to represent different concepts of accounts. For example, a shelf in a vault for gold bars or a specific location within a warehouse can be represented by providing additional information on an account implementation.

Account Freezing: an account can optionally implement the [Lockable](#) interface, allowing it to be frozen, i.e., temporarily disabling credits and debits.

17.4.3 Custom Instrument Implementations

Daml Finance provides default implementations for a wide range of financial instruments. However, we anticipate that specific requirements will lead to the adaptation of existing, or the creation of entirely new instrument types. The following are typical examples of when a custom instrument implementation is required:

Additional information: a custom instrument implementation might, for example, build upon the [Equity interface](#) to provide additional information pertinent to private equity (like share class, or liquidation preference).

New instrument types: if Daml Finance does not provide an implementation for a given instrument type, a custom implementation can be provided to fill that gap. The implementation can either leverage the [Contingent Claims](#) framework, as described in [this tutorial](#), or be implemented through standard interfaces, as seen in the implementation of the [Equity instrument](#).

17.4.4 Custom Lifecycle Implementations

Daml Finance provides a default set of lifecycle rules that can be used to evolve instruments. Examples are the implementation of [Distributions](#), [Replacements](#), or the [time-based evolution](#) of contingent-claims based instruments. There are many more lifecycle events and rules that can be implemented using the provided interfaces. Typically, implementations of the [Event](#) and [Rule](#) interface are required to handle new lifecycle events. Examples of events where a library extension might be warranted include:

- Credit events on bonds: our bond implementations don't provide an implementation for handling default events, as these are highly case-specific. A custom lifecycle event and rule implementation can provide the logic to handle the treatment of bond positions in case of default.
- Special corporate actions: a distribution that is either restricted to, or dependent on certain conditions can be implemented through a custom lifecycle implementation.
- Custom evolution logic: a non-fungible token following a specific evolution logic (i.e., it can be evolved under certain circumstances) can be implemented using custom lifecycle events and rules.

17.4.5 Custom Settlement Implementations

Daml Finance aims to provide a flexible and powerful mechanism to orchestrate asset settlement. There are cases, however, where a custom implementation might be required:

- Off-ledger integrations: specific information might be required to facilitate handling of settlement instructions in off-ledger rails. This could include, for example, information required to create SWIFT messages.
- Cross-ledger settlement: mechanisms like Hashed Timelock Contracts or custodial-bridged settlement might require a custom implementation of the settlement choices.

Chapter 18

Concepts

This section describes the core concepts of the Daml Finance library. It also refers the reader to where each of these concepts is implemented in the library.

The most important definitions are also summarized in the [glossary](#).

18.1 Asset Model

The library's asset model is the set of contracts that describe the financial rights and obligations that exist between parties. It is composed of instruments, holdings, and accounts.

18.1.1 Instrument

An instrument contract describes the economic terms (rights and obligations) of one unit of a financial contract.

It can be as simple as an ISIN code referencing some real-world (off-ledger) security, or it can encode specific on-ledger lifecycling logic.

Additionally, it specifies the instrument's holding standard or properties, which is described in more detail in the [Holding Standards](#) section.

18.1.1.1 Signatories

Every instrument must have an `issuer` party and a `depository` party, which are both signatories of the contract.

The terminology is borrowed from the real world. For example, an issuer of a stock instrument deposits the paper certificate at a depository and gets the corresponding amount credited in book-entry form.

On the ledger, the `depository` acts as a trusted party that prevents the `issuer` from potentially acting maliciously.

18.1.1.2 Keys and Versioning

Instruments are keyed by an [InstrumentKey](#), which comprises:

- the instrument `issuer`
- the instrument `depository`
- a textual `id`
- a textual `version`
- the instrument's `holdingStandard`

The version is used to keep track of the linear evolution of an instrument. For example, once a dividend on a share is paid, the version is used to identify the cum-dividend and the ex-dividend share.

18.1.1.3 Interfaces

Instrument interfaces are defined in the `Daml.Finance.Interface.Instrument.*` packages.

All instruments must implement the base interface, defined in [Daml.Finance.Interface.Instrument.Base.V4](#).

18.1.1.4 Implementations

A base implementation is provided in [Daml.Finance.Instrument.Token.V4](#).

This template does not define any lifecycling logic and is suitable to model contracts that are likely to stay stable, such as currency instruments.

The extension packages provide additional business-specific implementations, such as an [Equity](#) instrument (where the issuer can pay dividends) or a [Bond](#) instrument (which includes coupon payments).

The expectation is that customers define their own instruments suiting the use-case they are modeling.

18.1.2 Holding

A holding contract represents the ownership of a certain amount of an instrument by an owner at a custodian.

Whereas an instrument defines *what* a party holds (the rights and obligations), a holding defines *how much* (i.e., the amount) of an instrument and *against which party* (i.e., the custodian) the instrument is being held.

It is important to understand that the economic terms of an asset (the instrument) are separated from the representation of an asset holding. This allows centralized management of instruments (e.g. lifecycling) and the reuse of instruments and associated logic across different entities (e.g. custodians). It also avoids the data redundancy of replicating instrument data and logic on every holding contract.

18.1.2.1 Signatories

Every holding must have an `owner` party and a `custodian` party, which are usually both signatories of the contract.

The terminology is again borrowed from the real world: our cash or shares are usually deposited at a custodian and we have (at least in principle) the right to claim them back from the custodian at any given time.

18.1.2.2 Holding Standards

A holding implementation can have specific properties such as being *fungible* and/or *transferable*.

When, for instance, a holding is transferable, the ownership can be transferred to a different party at the same custodian.

These properties are exposed by letting a holding template implement the corresponding interfaces (*Fungible* and *Transferable*, respectively).

The library distinguishes four types of holdings, referred to as *Holding Standards*, namely:

1. *Fungible*: Holdings that are fungible only.
2. *Transferable*: Holdings that are transferable only.
3. *TransferableFungible*: Holdings that are both transferable and fungible.
4. *BaseHolding*: Holdings that are neither transferable nor fungible.

18.1.2.3 Interfaces

Holding interfaces are defined in the `Daml.Finance.Interface.Holding.V4` package. It consists of the interfaces *holding*, *transferable*, and *fungible*.

18.1.2.4 Implementations

`Daml.Finance.Holding.V4` provides implementations for each holding standard:

fungible only
transferable only
both transferable and fungible
neither transferable nor fungible

18.1.3 Account

Account contracts are used as proof of a relationship between a `custodian` and an `owner`.

An `owner` must have an account contract with a `custodian` before a holding contract can be created between the two parties.

This is similar to how, in the real world, you need to open a bank account before you can use the bank's services.

The account contract also controls which parties are authorized to transfer holdings in and out of the account. To be more precise, the *controllers* field of the account contains:

`outgoing`: a set of parties authorizing outgoing transfers
`incoming`: a set of parties authorizing incoming transfers

This allows for modeling various controllers of transfers between Alice's and Bob's accounts. For example:

`owners-controlled`: If the `owner` is the sole member the `outgoing` and `incoming` controllers for the accounts, a transfer of a holding from Alice's account to Bob's account needs to be authorized jointly by Alice and Bob.

`owner-only-controlled`: If, instead, there are no `incoming` controllers of Bob's account, it is enough that Alice authorizes the transfer alone.

`custodian-controlled`: If, as often is the case, the `custodian` needs to control what is being transferred, we can instead let the `custodian` be the sole member of `outgoing` and `incoming` controllers of the accounts.

Accounts also serve to prevent holding transfers to unvetted third parties: a holding of Alice can only be transferred to Bob if Bob has an account at the same Bank (and has therefore been vetted by the Bank).

18.1.3.1 Signatories

An account is co-signed by the account `owner` and the `custodian`.

18.1.3.2 Keys

Accounts are keyed by an [AccountKey](#), which comprises:

- the account `owner`
- the account `custodian`
- a textual `id`

18.1.3.3 Interfaces

The account interface is defined in the [Daml.Finance.Interface.Account.V4](#) package.

18.1.3.4 Implementations

A base account implementation is provided in [Daml.Finance.Account.V4](#).

The account can be created with arbitrary [controllers](#) (for incoming and outgoing transfers). Our examples typically let accounts be `owners-controlled`, i.e., both the current owner and the new owner must authorize transfers.

The account also implements the [Lockable](#) interface, enabling the freezing of an account, thus disabling credits and debits.

18.1.4 Example setups

We can now look at a few examples of how real-world rights and obligations can be modeled using the Daml Finance asset model.

18.1.4.1 Currency

We start by modeling a standard cash bank account. There are three parties involved: a Central Bank, a Commercial Bank, and a Retail Client.

The Central Bank defines the economic terms of the currency asset and is generally a highly trusted entity, therefore it acts as `issuer` as well as `depository` of the corresponding instrument.

We can use the [Token](#) instrument implementation for a currency asset, as we do not need any lifecycle logic.

The Retail Client has an [Account](#) at the Commercial Bank, with the former acting as `owner` and the latter as `custodian`.

Finally, the Retail Client is `owner` of a [transferable and fungible holding](#) at the Commercial Bank (i.e., the `custodian` in the contract). The holding references the currency instrument and the account.

In this scenario, we can see how:

- the instrument defines what is held

- the holding defines where the rights and obligations lie, as well as the corresponding amount

18.1.4.2 Equity

We now model units of shares held by an investor. There are three parties involved: an Issuing Entity, a Securities Depository, and an Investor.

The Issuing Entity acts as `issuer` of the [Equity Instrument](#). The Securities Depository acts as `depository` of the instrument, thus preventing the Issuing Entity from single-handedly modifying details of the instrument (such as the share's nominal value).

The Institutional Investor holds units of shares against the Securities Depository, through corresponding Account and Holding contracts.

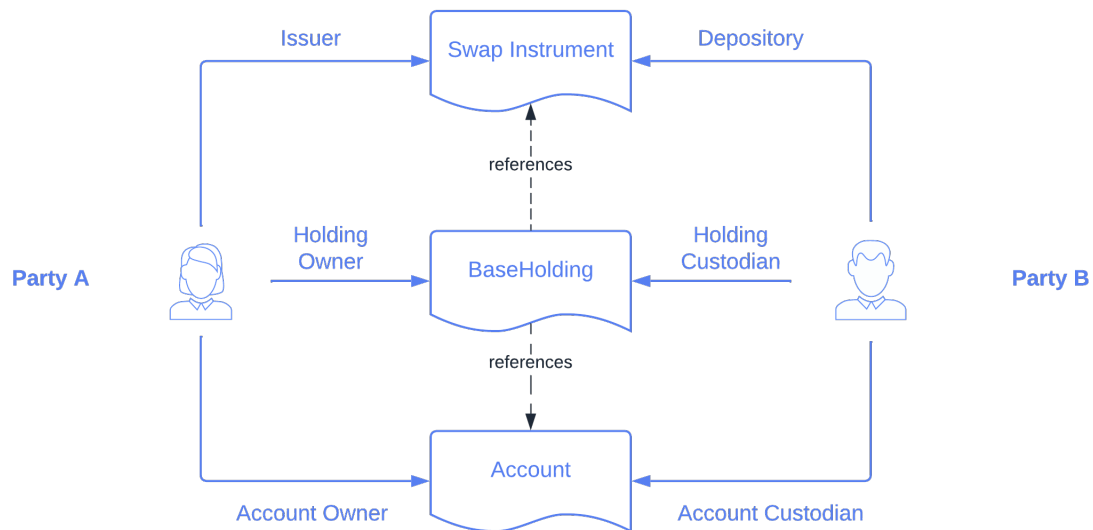

It is worth noting that the `issuer` of the Equity Instrument has the right to perform certain Corporate Actions, such as declaring dividends. This topic is covered in the [lifecycling](#) section.

18.1.4.3 OTC Swap

Finally, we model an OTC (over-the-counter) fixed vs. floating interest rate swap agreement between two parties, namely Party A and Party B. We can use the [Interest Rate Swap](#) instrument template for this purpose.

In this case, all contracts are agreed and co-signed by both parties. In the instrument contract, it does not really matter whether Party A is the `issuer` and Party B the `depository`, or the other way around. However, the role matters in the Holding contract, as it defines the direction of the trade, i.e., which party receives the fixed leg and which party receives the floating one.

18.2 Settlement

Settlement refers to the execution of holding transfers originating from a financial transaction.

Daml Finance provides facilities to execute these transfers atomically (i.e., within the same Daml transaction). Interfaces are defined in the `Daml.Finance.Interface.Settlement.V4` package, whereas implementations are provided in the `Daml.Finance.Settlement.V4` package.

In this section, we first illustrate the settlement workflow with the help of an example FX transaction, where Alice transfers a EUR-denominated holding to Bob, in exchange for a USD-denominated holding of the same amount.

We then delve into the details of each of the settlement components.

18.2.1 Workflow

Our initial state looks as follows:

Alice owns a holding on a `EUR` instrument, for an amount of 1000

Bob owns a holding on a `USD` instrument, for an amount of 1000

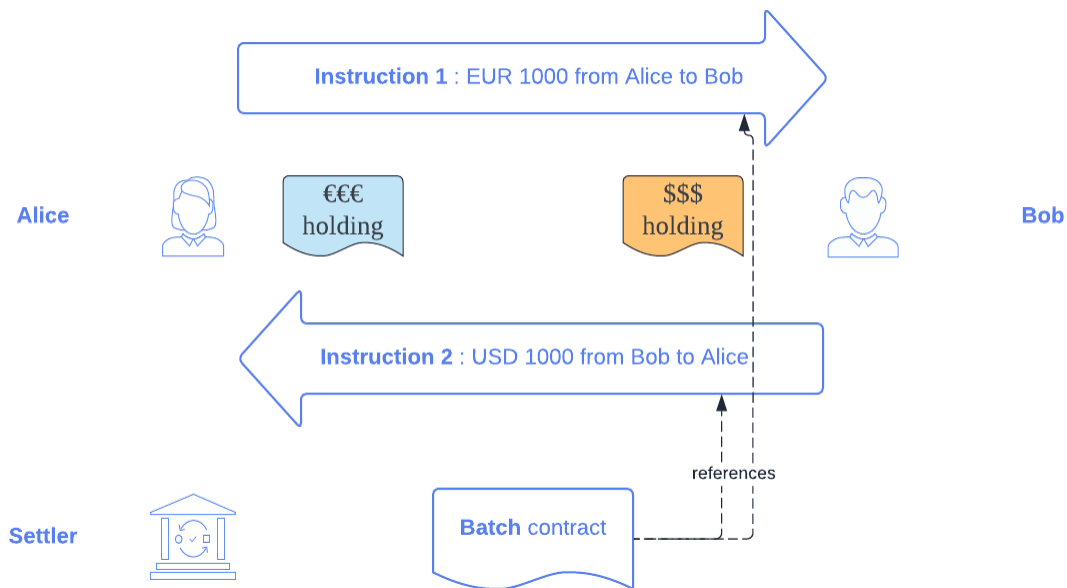

These holdings are generally held at different custodians.

18.2.1.1 Instruct

Alice and Bob want to exchange their holdings and agree to enter into the transaction by being signatories on a transaction contract. Settlement can then be instructed which results in 3 contract instances being created:

1. an *Instruction* to transfer EUR 1000 from Alice to Bob
2. an *Instruction* to transfer USD 1000 from Bob to Alice
3. a *Batch* used to execute the above Instructions

Each instruction defines who is the sender, who is the receiver, and what should be transferred (instrument and amount) at which custodian.

18.2.1.2 Allocate and Approve

In order to execute the FX transaction, we first need to:

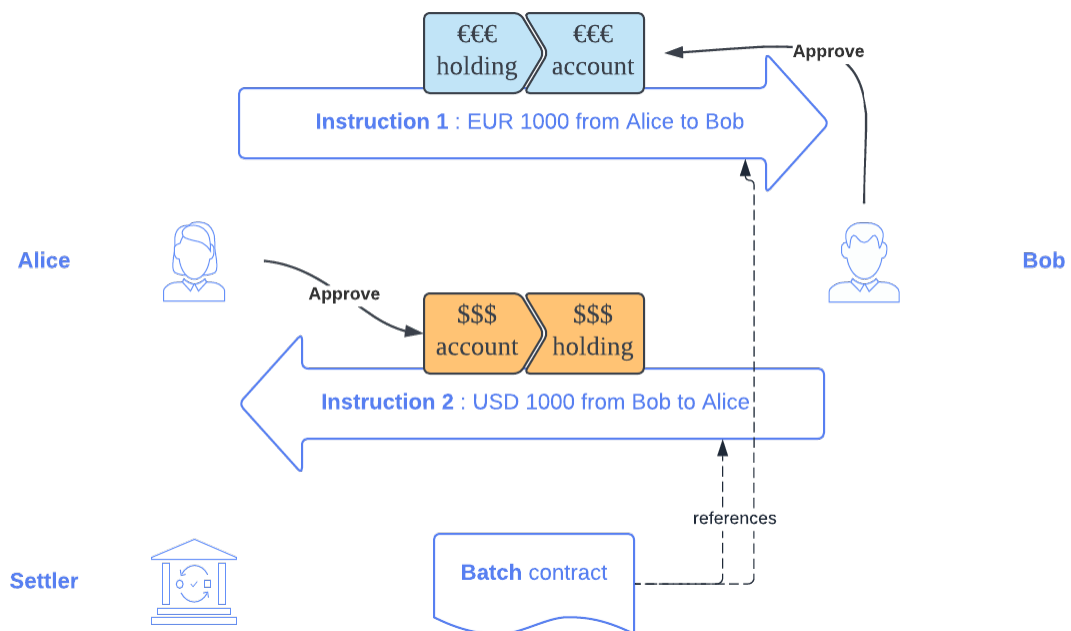

- allocate, i.e., specify which holding should be used
- approve, i.e., specify to which account the asset should be transferred

Allocation and approval is required for each *Instruction*.

Alice *allocates* the instruction where she is the sender by pledging her holding. Bob does the same on the instruction where he is the sender.

Each receiver can then specify to which account the holding should be sent by *approving* the corresponding instruction.

18.2.1.3 Execute

Once both instructions are allocated and approved, a Settler party uses the [Batch](#) contract to [execute](#) them and finalize settlement in one atomic transaction.

The instructions and the batch are archived following a successful execution.

18.2.1.4 Remarks

There are some assumptions that need to hold in order for the settlement to work in practice:

- Bob needs to have an account at the custodian where Alice's holding is held and vice versa (for an example with intermediaries, see [Route provider](#) below).

- Both holdings need to be [Transferable](#)

- The transfer must be fully authorized (i.e., the parties allocating and approving an instruction must be the controllers of outgoing and incoming transfers of the corresponding accounts, respectively)

Also, note that the allocation and approval steps can happen in any order.

18.2.2 The components in detail

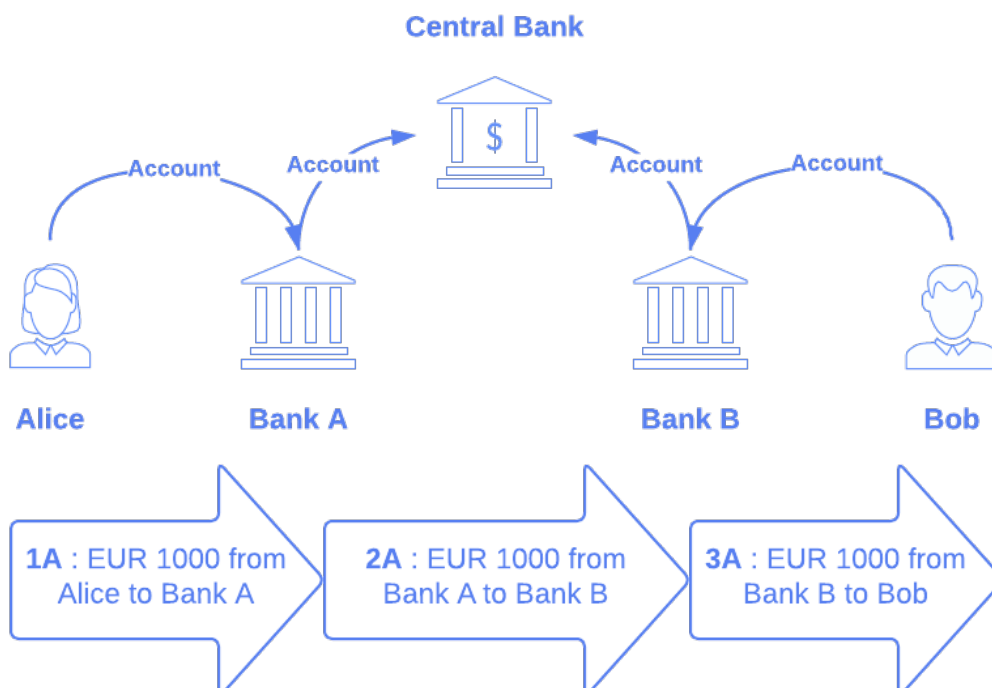

18.2.2.1 Route provider

When a transfer requires intermediaries to be involved, the role of a [Route Provider](#) becomes important. Let us assume, for instance, that Alice's EUR holding in the example above is held at Bank A, whereas Bob has a EUR account at Bank B. Bank A and Bank B both have accounts at the Central Bank.

In this case, a direct holding transfer from Alice to Bob cannot generally be instructed. The original *Instruction* between Alice and Bob needs to be replaced by three separate *Instructions*:

- 1A:** Alice sends EUR 1000 (held at Bank A) to Bank A
- 1B:** Bank A sends EUR 1000 (held at the Central Bank) to Bank B.
- 1C:** Bank B credits EUR 1000 to Bob's account (held at Bank B)

We refer to this scenario as *settlement with intermediaries*, or just *intermediated settlement*.

The Route Provider is used to discover a settlement route, i.e., *routed steps*, for each settlement *step*.

18.2.2.2 Settlement factory

The [Settlement Factory](#) is used to instruct settlement, i.e., create the [Batch](#) contract and the settlement [Instructions](#), from [routed steps](#), so that they can be allocated and approved by the respective parties.

18.2.2.3 Instruction

The [Instruction](#) is used to settle a single holding transfer at a specific custodian, once it is allocated and approved.

In the [Allocation](#) step, the sender acknowledges the transfer and determines how to send the holding. This is usually done by allocating with a [Pledge](#) of the sender's existing holding (which has the correct instrument quantity) at the custodian. When the sender is also the custodian, the instruction can be allocated with [CreditReceiver](#). In this case, a new holding is directly credited into the receiver's account.

In the [Approval](#) step, the receiver acknowledges the transfer and determines how to receive the holding. This is usually done by approving with [TakeDelivery](#) to one of the receiver's accounts at the custodian. When the receiver is also the incoming holding's custodian, the instruction can be approved with [DebitSender](#). In this case, the holding is directly debited from the sender's account. A holding owned by the custodian at the custodian has no economical value, it is a liability against themselves and can therefore be archived without consequence.

To clarify these concepts, here is how the 3 instructions in the intermediated example above would be allocated / approved.

Instruction	Allocation	Approval
1A : EUR 1000 from Alice to Bank A @ Bank A	Alice pledges her holding	Bank A approves with DebitSender
1B : EUR 1000 from Bank A to Bank B @ Central Bank	Bank A pledges its holding	Bank B takes delivery to its account
1C : EUR 1000 from Bank B to Bob @ Bank B	Bank B allocates with CreditReceiver	Bob takes delivery to his account

Finally, the [Instruction](#) supports two additional settlement modes:

Any instruction can settle off-ledger (if the stakeholders agree to do so). For this to work, we require the custodian and the sender to jointly allocate the instruction with a [SettleOffledger](#), and the custodian and the receiver to jointly approve the instruction with a [SettleOffledgerAcknowledgement](#).

A special case occurs when a transfer happens via an intermediary at the same custodian, i.e., we have 2 instructions having the same custodian and instrument quantity (in a batch), and the receiver of the first instruction is the same as the sender of the second instruction. In this case, we allow the holding received from the first instruction to be passed through to settle the second instruction, i.e., without using any pre-existing holding of the intermediary. For this to work, the first instruction is approved with [PassThroughTo](#) (i.e., pass through to the second instruction), and the second instruction is allocated with [PassThroughFrom](#) (i.e., pass through from the first instruction). An intermediary account used for the passthrough is thereby also to be specified.

18.2.2.4 Batch

The [Batch](#) is used to execute a set of instructions atomically. Execution will fail if any of the [Instructions](#) is not fully allocated / approved, or if the transfer is unsuccessful.

18.2.2.5 Settlement Time

The settlement time for financial transactions can vary based on the market and the type of securities involved. Typically, settlement periods are denoted as T+1, T+2, or T+3, indicating the transaction date plus one, two, or three business days, respectively. Some markets may also offer real-time settlement options. It's also common for certain trades between parties to have unique, mutually agreed-upon settlement periods.

The [Batch](#) and [Instruction](#) implementations are designed to allow the optional setting of a preferred settlement time, without any mechanisms that enforce a specific settlement time. This design choice offers several advantages:

Settlement Time Flexibility: The Settler party has the discretion to decide or defer the actual settlement time. This includes the ability to settle transactions after the designated settlement time, which can be particularly useful in resolving any off-ledger disputes.

Avoidance of Early Settlement: Parties involved in sending or receiving a holding may opt to delay their [allocation](#) or [approval](#) of an instruction until just prior to the settlement time. This strategy prevents the [Batch](#) from settling prematurely.

Handling of Late Settlements: To address cases where parties fail to settle by the desired time, we propose using a separate custom contract instance. This contract could facilitate the rolling of a [Batch](#) (along with its [Instructions](#)) into a subsequent settlement cycle if the initial settlement period lapses. Additionally, the contract could allow for imposing penalties on parties that fail to allocate or approve the transaction in a timely manner.

For scenarios requiring a more stringent settlement process, customers are welcome to provide their own implementation. This custom implementation can include specific checks and controls tailored to their particular needs and requirements.

18.2.3 Remarks and further references

The settlement concepts are also explored in the [Settlement tutorial](#).

18.3 Lifecycling

[Lifecycling](#) refers to the evolution of financial instruments over their lifetime. This includes processing of contractual events, like interest payments or coupon cashflows, as well as discretionary events, like dividends and other corporate actions. The library provides a standard mechanism for processing such events across different instruments. The output is not limited to cash but can also include the distribution of other asset types.

The interfaces for lifecycling are defined in the `Daml.Finance.Interface.Lifecycle.V4` package, and several default implementations are provided in the `Daml.Finance.Lifecycle.V4` package.

In this section, we first motivate the particular approach to lifecycling in Daml Finance. We then explain the process in detail using the example of a cash dividend event. Finally, we describe each of the involved components in depth.

18.3.1 Approach

18.3.1.1 Single Source of Truth

A general principle we follow in Daml Finance is that there should only be a single instance of any given instrument on the ledger. This instance is centrally maintained by the issuer of the instrument, with the possibility for a depository to act as an additional, third-party trust anchor. As part of lifecycling, this single instance of the instrument produces lifecycle effects, which are then used across all parties on the ledger as a single source of truth for how to process a certain event. This avoids any duplication of lifecycling logic or redundant processing of instruments, and therefore removes the need for reconciliation across parties involved in the process.

18.3.1.2 Instrument Versioning

In current financial markets instruments are usually referenced by a textual identifier, like an ISIN or CUSIP number. When a particular corporate action is processed on its effective date the instrument referred to by an identifier changes implicitly. As an example, the ISIN for a stock refers to the `cum-dividend` instrument (where holders are still entitled to the dividend) up until the `ex-dividend` date. From the `ex-dividend` date onwards the same ISIN refers to the `ex-dividend` instrument, so any stock acquired on or after that date is not entitled to the dividend anymore. This leads to a lot of complexity during processing of such corporate actions. In particular, it forces these events to be processed in a `big bang` approach, as a consistent snapshot of holdings needs to be taken to determine the rightful recipients of any resulting cashflows and other [effects](#).

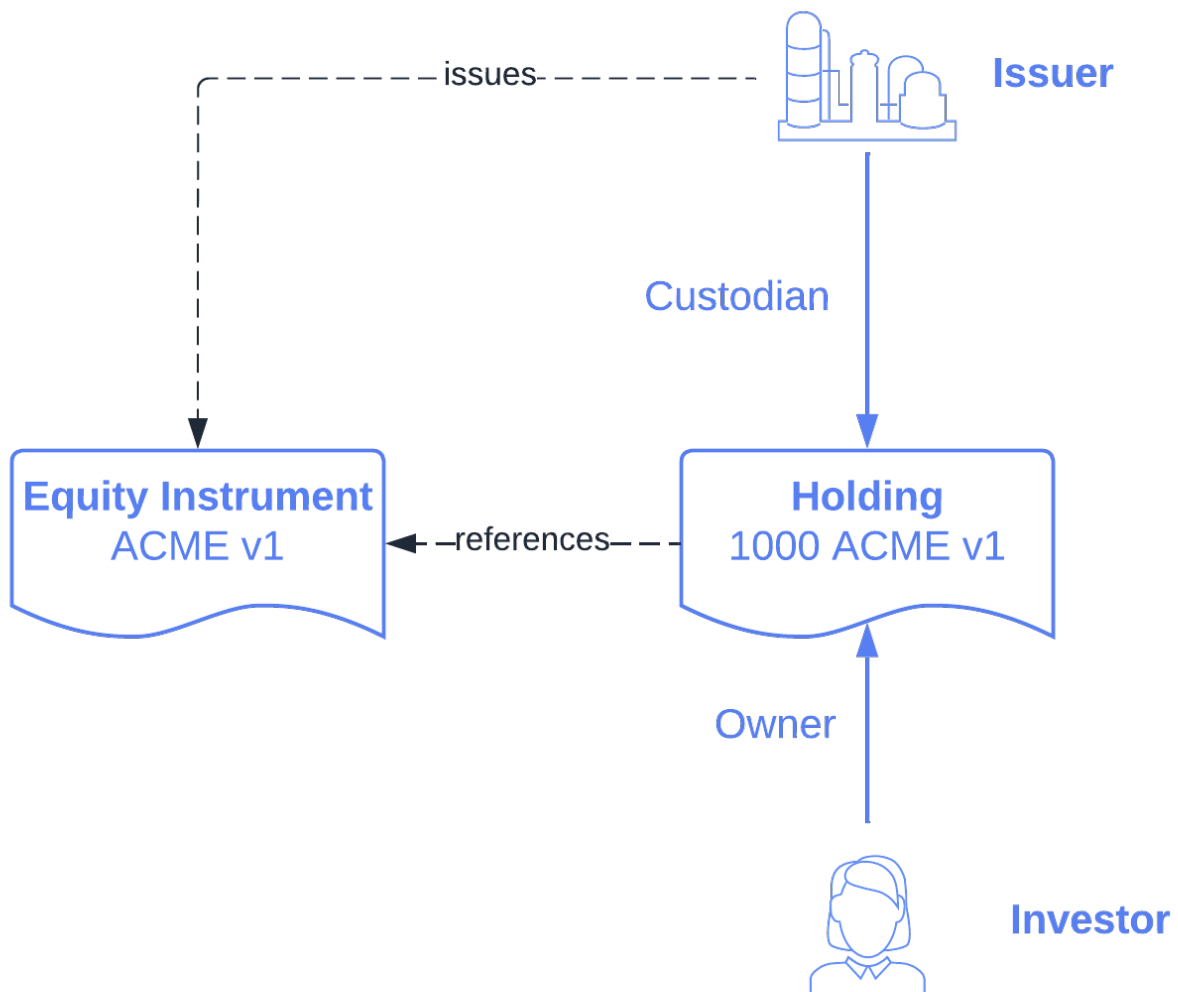

In Daml Finance we aim for a more efficient and flexible operating model for processing lifecycle events. All instruments are strictly versioned so that we can clearly differentiate between the `cum`- and `ex`-event version of an instrument. This means that it is perfectly safe for those versions to co-exist at the same time, and it allows for a gradual transition from one version to another. Generally, the issuer of an instrument is responsible for creating and maintaining instrument versions, and for producing the [effects](#) of a particular lifecycle event. During the lifecycle process, holders of this instrument will migrate their holdings to a new version of the instrument while at the same time claiming any resulting [effects](#) from the event.

Versions are usually considered opaque strings, but one can follow a numerical versioning scheme if an instrument is known to have linear evolution (i.e., there is no optionality that can result in two different evolution paths).

18.3.2 Workflow

In this scenario we go through the process of paying a cash dividend from an issuer to an investor. The initial state looks as follows:

- An issuer maintains an `ACME` instrument representing shares in a company
- An investor owns a holding of 1000 units of the `ACME` instrument (version 1) with the issuer
- The issuer wants to process and pay a cash dividend of USD 10.0 per unit of its `ACME` instrument (version 1)

We will now explain each step in the process in detail. The goal is that every holder of a v1 cum-dividend instrument will afterwards have \$10 (for each unit of instrument held) and a holding on the v2 ex-dividend instrument.

18.3.2.1 Creating the event

The issuer first creates a new instance of the `ACME` instrument, assigning a new version. The new version is then automatically produced when processing the event as described in the next step.

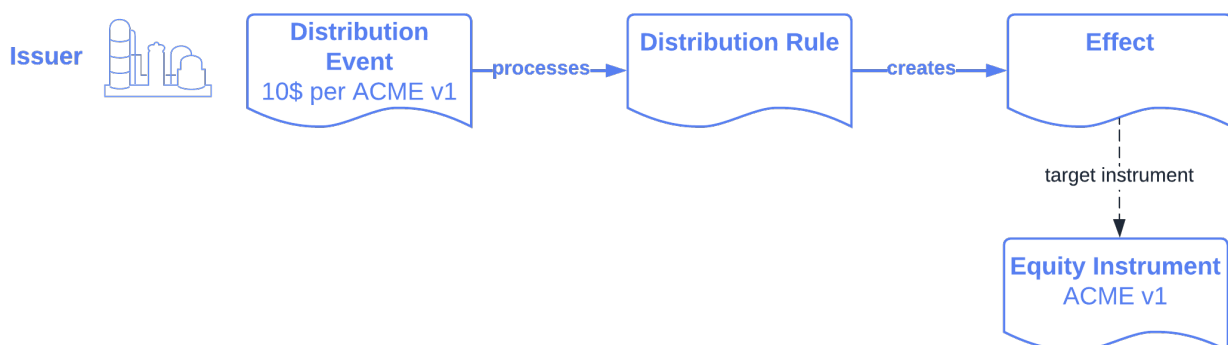

Now, the issuer creates a lifecycle event defining the terms of dividend. In our example we can use the `DistributeDividend` choice on the `Equity` instrument to create such an event. This is merely a convenience choice available for equities, any workflow can be used to create new instrument versions and associated lifecycle events.

Note that only one instrument (the v1) is paying a dividend. The lifecycle event is used to evolve the v1 contract into a v2 that does not pay dividends.

18.3.2.2 Processing the event

The event is now passed into a `Distribution Rule`, which generates the `Lifecycle Effect` describing the distribution of assets per unit of `ACME` stock. The effect refers to a `targetInstrument`, which is the version of the instrument that can be used by stock holders to claim the cash dividend according to the number of stocks held. By being tied to a specific version we prevent holders from (accidentally or intentionally) claiming a particular effect twice.

These components are described in more detail in the [Components](#) section below. For simplicity, we have chosen a dividend as an example here, but the same workflow can be used to process more complex events. Note that the logic to create the new version of an instrument can also be encoded in the lifecycle rule.

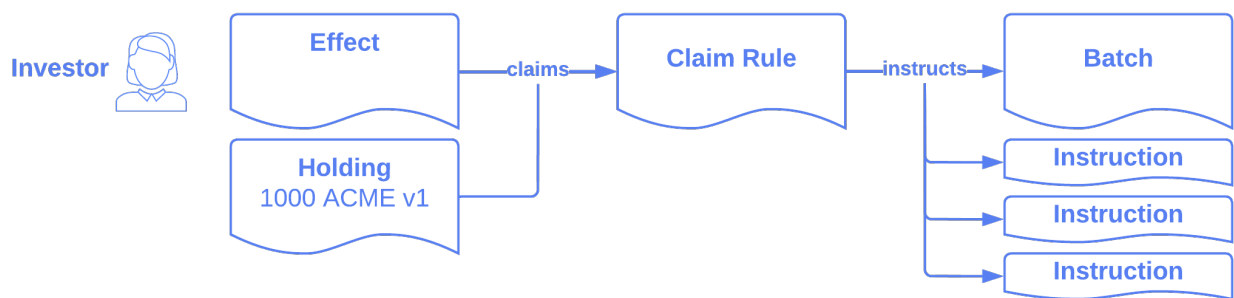

18.3.2.3 Claiming the effect

The investor can now present its holding of ACME stock along with the corresponding [Effect](#) to a [Claim Rule](#). This will instruct settlement for:

The exchange of ACME stock versions held: the investor sends back the old version, and receives the new one

The payment of the cash dividend amount corresponding to the number of stocks held

Both legs of this settlement are grouped in a [Batch](#) to provide atomicity. The goal of the batch is to exchange a holding on the v1 instrument for a holding on the v2 instrument + \$10 (for each share held). This ensures that the investor can never claim a dividend twice, as after settlement they only hold the new version of the stock, which is not entitled to the dividend anymore.

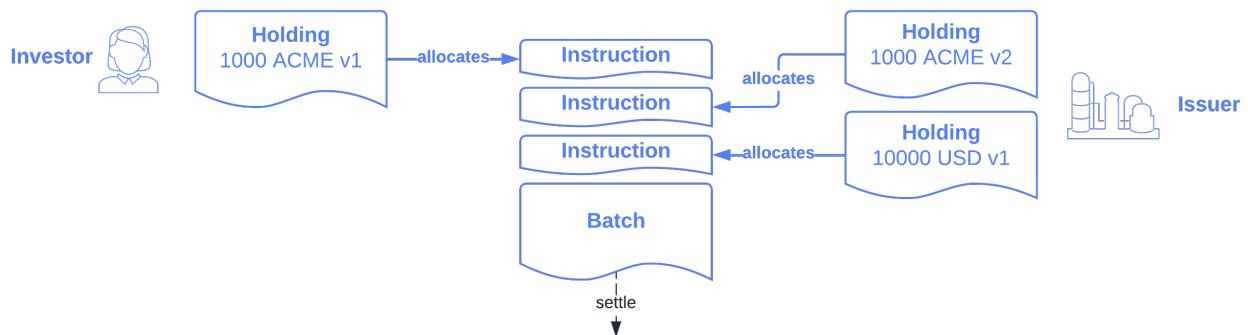

Note that the party responsible for claiming an effect can be specified flexibly in the [Claim Rule](#) contract. Through this contract, custodians can be given the authority to push a given corporate action to the asset holder as is common in current operating procedures.

The model also supports atomic, intermediated settlement of lifecycle events. For example, if a dividend is to be settled between issuer, custodian, and investor in a single transaction, the custodian (having visibility of both its holding at the issuer and the investor's holding) can pass in both holdings into the claim rule, and thereby instruct a single batch to settle both sides.

18.3.2.4 Settlement

The batch and instructions resulting from claiming an effect can now be settled as described in the [Settlement](#) section of the documentation.

The following picture shows the three asset movements involved in this particular example:

The result of processing the settlement batch results in the investor receiving a 10000 USD dividend and 1000 shares of `ACME v2` in return for their 1000 shares of `ACME v1`.

18.3.3 Components

18.3.3.1 Events

An event contract is used to indicate that a certain action has occurred, which might trigger the lifecycling of certain instruments. In the context of the dividend example above, this is the Issuer declaring a `Cash Dividend` to be paid on a specific stock.

Events implement the [Event](#) interface, which describes basic properties of a lifecycle event:

- The event providers
- The event identifier and description
- The event timestamp

Different implementations exist to cover typical corporate actions:

The [Distribution](#) event can be used to distribute assets to holders of an instrument. This covers cash-, share-, and mixed dividends, rights issues, or the distribution of voting rights.

The [Replacement](#) event handles replacements of one instrument for another with support for a factor. This covers corporate actions like (reverse) stock splits, mergers, and spin-offs.

A single event can be used as a trigger to lifecycle multiple instruments.

18.3.3.2 Lifecycle Rule

A [Lifecycle Rule](#) is used to process an event for a certain instrument and calculate the resulting lifecycle effects.

A lifecycle rule can either assume that a new version of the instrument has already been created (as is the case for the [Distribution](#) and [Replacement](#) rules), or it can create the new version of the instrument as part of its implementation. The latter can be useful if information required to create the new version is only available upon processing of the event, as is the case for the evolution of the [Generic Instrument](#), as well as other [Contingent Claims](#) based instruments.

Lifecycling of Contingent Claims based instruments can be divided into two categories:

Time based evolution: An instrument is evolved solely due to the passage of time. An example is a fixed coupon bond, where a coupon payment is due at the end of every coupon period. This can be *automatically* lifecycled by providing the event time (and any observables required). The tutorial [Time-based lifecycling \(using a fixed rate bond\)](#) describes how this is done.

Election based evolution: An instrument is evolved as a result of a *manual* election. One example is a callable bond, where the custodian of the corresponding holding has the right (but not the obligation) to call, or redeem early, the instrument on certain call dates. Lifecycling of such an instrument requires an *Election* event. Time alone is not sufficient, because the evolution of the instrument depends on manual actions of the holding stakeholders. Check out the tutorial [Election-based lifecycling \(using a callable bond\)](#) for more details on how this can be implemented in practice.

Note that some instruments can require both types of lifecycling. An example of this is a callable bond that is callable only on some of the coupon dates.

18.3.3.3 Effects

An [Effect](#) describes the asset movements resulting from a particular event. It specifies these movements per unit of a target instrument and version.

In the dividend example, the effect describes the following asset movement:

- give a unit of a v1 holding
- receive a unit of a v2 holding
- receive \$10

Holdings on this specific instrument version entitle a holder to claim the effect, which results in the required asset movements to be instructed.

18.3.3.4 Claim Rule

The [Claim Rule](#) is used by instrument holders to claim lifecycle effects and instruct settlement of the resulting asset movements.

Each effect specifies a target instrument (and version), and holdings on this instrument (version) are required to claim an effect.

In the dividend example, the v1 instrument is the target instrument. A holding on a v1 instrument serves as proof of ownership such that there is no need for an issuer to take a consistent snapshot of holdings as of a specific date.

The output of the claim rule is a [Settlement Batch](#) and a set of [Instruction](#)s that settle the asset movements atomically.

Note that multiple holdings can be passed into the claim rule in order to instruct intermediated settlement of an effect, or to instruct atomic settlement for multiple asset holders at the same time.

18.3.4 Remarks and further references

The [Lifecycling tutorial](#) describes how these components are used in practice.

Chapter 19

Instruments

This section describes which instruments are included out of the box in Daml Finance. Each instrument package contains a list of supported instruments. The instrument extension pages explain what each instrument does and how to set it up.

19.1 Bonds

The following instruments are included in the [Bond Instrument package](#):

- Fixed rate bonds
- Floating rate bonds
- Callable bonds
- Inflation linked bonds
- Zero coupon bonds

19.2 Equities

The following instruments are included in the [Equity Instrument package](#):

- Equities (can also be used to model ETFs)

19.3 Options

The following instruments are included in the [Option Instrument package](#):

- Cash-settled European options
- Physically-settled European options
- Barrier options
- Dividend options

19.4 Structured Products

The following instruments are included in the [Structured Products Instrument package](#):

- Barrier reverse convertible

19.5 Swaps

The following instruments are included in the [Swap Instrument package](#):

- Interest rate swaps
- Currency swaps
- Foreign exchange swaps
- Credit default swaps
- Asset swaps
- FpML swaps (supports the above swap types using the FpML schema)

19.6 Other Instruments

In addition to the above instruments, which model specific payoffs, the library provides

- a [Token Instrument](#), whose terms are defined by a simple textual label
- a [Generic Instrument](#), which provides a flexible framework to structure user-defined payoffs and lifecycle them on the ledger

19.7 Token Instrument

A Token is a simple instrument template whose economic terms on the ledger are defined by two textual fields, namely an `id` and a `description`.

It is often used to model financial instruments that do not exhibit complex lifecycling logic, such as currencies.

19.7.1 How to create a Token Instrument

The following code snippets are taken from the [Getting Started tutorial](#), which you can install using the Daml assistant.

In order to instantiate a Token Instrument, we first need to create the corresponding instrument factory template

```
tokenFactoryCid <- toInterfaceContractId @TokenFactory.I <$> submit bank do
  createCmd Token.Factory with
    provider = bank
    observers = mempty
```

We can then specify the terms of the instrument and exercise the `Create` choice in the factory to create the token.

```
let
  instrumentId = Id "USD"
  instrumentVersion = "0"
  instrumentKey = InstrumentKey with
    issuer = bank
    depository = bank
    id = instrumentId
    version = instrumentVersion
    holdingStandard = TransferableFungible
now <- getTime

submit bank do
  exerciseCmd tokenFactoryCid TokenFactory.Create with
    token = Token with
      instrument = instrumentKey
      description = "Instrument representing units of a generic token"
      validAsOf = now
      observers = mempty
```

19.7.2 How to lifecycle a Token Instrument

Generic corporate actions, such as [Distribution events](#), can be applied to Token Instruments. The [Lifecycle](#) section of the Getting Started tutorial shows how this is done in detail.

19.7.3 Frequently Asked Questions

19.7.3.1 How do I transfer or trade a Token Instrument?

When you have created a holding on a token instrument this can be transferred to another party. This is described in the [Getting Started: Transfer](#) tutorial.

In order to trade a token (transfer it in exchange for cash) you can also initiate a delivery versus payment with atomic settlement. This is described in the [Getting Started: Settlement](#) tutorial.

19.8 Bond Instrument

To follow the code snippets used in this page in Daml Studio, you can [clone the Daml Finance repository](#) and run the scripts included in the [Instrument/Bond/Test](#) folder.

19.8.1 How to use a Bond Instrument in your application

As explained in the [Getting Started](#) section and on the [Architecture](#) page, your app should only depend on the interface layer of Daml Finance. For bonds this means that you should only include the [bond interface package](#).

Your initialization scripts are an exception, since they are only run once when your app is initialized. These are used to create the necessary instrument factories. Your app can then create bond instruments through these factory contracts.

19.8.2 How to Create a Bond Instrument

There are different types of bonds, which mainly differ in the way the coupon is defined. In order to create a bond instrument you first have to decide what type of bond you need. The [bond instrument package](#) currently supports the following bond types:

19.8.2.1 Fixed Rate

[Fixed rate bonds](#) pay a constant coupon rate at the end of each coupon period. The coupon is quoted on a yearly basis (per annum, p.a.), but it could be paid more frequently (e.g. quarterly). For example, a bond could have a 2% p.a. coupon and a 6M coupon period. That would mean a 1% coupon is paid twice a year.

As an example we will create a bond instrument paying a 1.1% p.a. coupon with a 12M coupon period. This example is taken from [Instrument/Bond/Test/FixedRate.daml](#), where all the details are available.

We start by defining the terms:

```
let
  issueDate = date 2019 Jan 16
  firstCouponDate = date 2019 May 15
  maturityDate = date 2020 May 15
  notional = 1.0
  couponRate = 0.011
  couponPeriod = M
  couponPeriodMultiplier = 12
  dayCountConvention = Act365Fixed
  businessDayConvention = Following
```

The [day count convention](#) is used to determine how many days, i.e., what fraction of a full year, each coupon period has. This will determine the exact coupon amount that will be paid each period.

The [business day convention](#) determines how a coupon date is adjusted if it falls on a non-business day.

We also need holiday calendars, which determine *when* to adjust dates.

We can use these variables to create a [PeriodicSchedule](#):

```
let
  (y, m, d) = toGregorian firstCouponDate
  periodicSchedule = PeriodicSchedule with
    businessDayAdjustment =
      BusinessDayAdjustment with
        calendarIds = holidayCalendarIds
        convention = businessDayConvention
    effectiveDateBusinessDayAdjustment = None
    terminationDateBusinessDayAdjustment = None
    frequency =
      Periodic Frequency with
        rollConvention = DOM d
        period = Period with
          period = couponPeriod
          periodMultiplier = couponPeriodMultiplier
    effectiveDate = issueDate
```

(continues on next page)

(continued from previous page)

```
firstRegularPeriodStartDate = Some firstCouponDate
lastRegularPeriodEndDate = Some maturityDate
stubPeriodType = None
terminationDate = maturityDate
```

This is used to determine the periods that are used to calculate the coupon. There are a few things to note here:

The [RollConventionEnum](#) defines whether dates are rolled at the end of the month or on a given date of the month. In our example above, we went for the latter option.

The [StubPeriodTypeEnum](#) allows you to explicitly specify what kind of stub period the bond should have. This is optional and not used in the example above. Instead, we defined the stub implicitly by specifying a `firstRegularPeriodStartDate`: since the time between the issue date and the first regular period start date is less than 12M (our regular coupon period), this implies a short initial stub period.

For more information on calendar, schedule, and day count functions, see the [date utility functions tutorial](#).

Now that we have defined the terms we can create the bond instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd fixedRateBondFactoryCid FixedRateBondFactory.Create with
    fixedRate = FixedRate with
      instrument
      description
      couponRate
      periodicSchedule
      holidayCalendarIds
      calendarDataProvider
      dayCountConvention
      currency
      notional
      lastEventTimestamp
    observers = fromList observers
```

Once this is done, you can create a holding on it using [Account.Credit](#).

19.8.2.2 Floating Rate

[Floating rate bonds](#) pay a coupon which is determined by a reference rate. There is also a rate spread, which is paid in addition to the reference rate.

Here is an example of a bond paying Euribor 3M + 1.1% p.a. with a 3M coupon period:

```
let
  issueDate = date 2019 Jan 16
  firstCouponDate = date 2019 Feb 15
  maturityDate = date 2019 May 15
  referenceRateId = "EUR/EURIBOR/3M"
  floatingRate = FloatingRate with
    referenceRateId
    referenceRateType = SingleFixing CalculationPeriodStartDate
    fixingDates = DateOffset with
      periodMultiplier = 0
      period = D
      dayType = Some Business
      businessDayConvention = NoAdjustment
      businessCenters = ["EUR"]
  notional = 1.0
  couponSpread = 0.011
  couponPeriod = M
  couponPeriodMultiplier = 3
  dayCountConvention = Act365Fixed
  businessDayConvention = Following
```

The instrument supports two types of reference rates, which are configurable using the [ReferenceRateTypeEnum](#):

- Libor/Euribor style rates with a single fixing
- SOFR style reference rates (using a compounded index)

Using these terms we can create the floating rate bond instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd floatingRateBondFactoryCid FloatingRateBondFactory.Create with
    floatingRate = FloatingRateBond.FloatingRate with
      instrument
      description
      floatingRate
      couponSpread
      periodicSchedule
      holidayCalendarIds
      calendarDataProvider
      dayCountConvention
      currency
      notional
```

(continues on next page)

(continued from previous page)

```
lastEventTimestamp
observers = fromList observers
```

The reference rate (Euribor 3M) is observed once at the beginning of each coupon period and used for the coupon payment at the end of that period.

19.8.2.3 Callable

[Callable bonds](#) are similar to the bonds above, but in addition they can be redeemed by the issuer before maturity. The callability is restricted to some (or all) of the coupon dates. In other words, these bonds have a *Bermudan* style embedded call option.

Both fixed and floating rate coupons are supported by this instrument. In case of a floating rate, there is often a fixed spread as well. This can be represented by a fixed rate coupon, which is shown in the following example. Here is a bond paying Libor 3M + 0.1% p.a. with a 3M coupon period:

```
-- Libor + 0.1% coupon every 3M (with a 0% floor and a 1.5% cap)
let
  rollDay = 15
  issueDate = date 2022 Jan rollDay
  firstCouponDate = date 2022 Apr rollDay
  maturityDate = date 2024 Jan rollDay
  notional = 1.0
  couponRate = 0.001
  capRate = Some 0.015
  floorRate = Some $ 0.0
  couponPeriod = M
  couponPeriodMultiplier = 3
  dayCountConvention = Act360
  useAdjustedDatesForDcf = True
  businessDayConvention = Following
  referenceRateId = "USD/LIBOR/3M"
  floatingRate = Some FloatingRate with
    referenceRateId
    referenceRateType = SingleFixing CalculationPeriodStartDate
    fixingDates = DateOffset with
      periodMultiplier = -2
      period = D
      dayType = Some Business
      businessDayConvention = NoAdjustment
      businessCenters = ["USD"]
```

The coupon rate in this example also has a 0% floor and a 1.5% cap. This is configurable, just set the cap or floor to *None* if it does not apply.

The fixed rate is fairly simple to define, but the floating rate requires more inputs. A [FloatingRate](#) data type is used to specify which reference rate should be used and on which date the reference rate is fixed for each coupon period.

The above variables can be used to create a *couponSchedule*:

```
couponSchedule = createPaymentPeriodicSchedule firstCouponDate
  holidayCalendarIds
  businessDayConvention couponPeriod couponPeriodMultiplier issueDate
  maturityDate
```

(continues on next page)

(continued from previous page)

This `couponSchedule` is used to determine the coupon payment dates, where the `businessDayConvention` specifies how dates are adjusted. Also, `useAdjustedDatesForDcf` determines whether adjusted or unadjusted dates should be used for day count fractions (to determine the coupon amount).

In addition to the Libor/Euribor style reference rates, compounded SOFR and similar reference rates are also supported. In order to optimize performance, these compounded rates are calculated via a (pre-computed) continuously compounded index, as described in the [ReferenceRateTypeEnum](#). For example, here is how *daily compounded SOFR* can be specified using the `SOFR Index`:

```
referenceRateId = "SOFR/INDEX"
floatingRate = Some FloatingRate with
  referenceRateId
  referenceRateType = CompoundedIndex Act360
```

This instrument also allows you to configure on which coupon dates the bond is callable. This is done by specifying a separate `callSchedule`. The bond is callable on the *last* date of each schedule period. For example, if the bond is callable on every coupon date, simply set `callSchedule = couponSchedule`. Alternatively, if the bond is only callable every six months, this can be configured by specifying a different schedule:

```
-- Define a schedule for callability. The bond is callable on the *last* date
-- of each schedule
-- period.
-- In this example, it is possible to call the bond every 6M (every second
-- coupon date).
callScheduleStartDate = issueDate
callScheduleEndDate = maturityDate
callPeriod = couponPeriod
callPeriodMultiplier = 6
callScheduleFirstRegular = None -- Only used in case of an irregular schedule
callSchedule = createPeriodicSchedule callScheduleFirstRegular
-- holidayCalendarIds
businessDayConvention callPeriod callPeriodMultiplier callScheduleStartDate
callScheduleEndDate rollDay
noticeDays = 5
```

The `noticeDays` field defines how many business days notice is required to call the bond. The election whether or not to call the bond must be done on this date.

Using these terms we can create the callable bond instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd callableBondFactoryCid CallableBondFactory.Create with
    callable = Callable with
      instrument
```

(continues on next page)

(continued from previous page)

```

description
floatingRate
couponRate
capRate
floorRate
couponSchedule
noticeDays
callSchedule
holidayCalendarIds
calendarDataProvider
dayCountConvention
useAdjustedDatesForDcf
currency
notional
lastEventTimestamp
prevEvents = []
observers = fromList observers

```

Unlike regular fixed and floating bonds, which are lifecycled based on the passage of time, this callable bond instrument contains an embedded option that is not automatically exercised. Instead, the custodian of the bond holding must manually decide whether or not to call the bond. This is done by making an *Election*.

This callable bond example is taken from [Instrument/Bond/Test/Callable.daml](#), where all the details are available. Also, check out the [Election based lifecycling tutorial](#) for more details on how to define and process an *Election* in practice. Note that the sample bond above, which is callable only on some of the coupon dates, will require two types of lifecycling:

[Time based lifecycling](#) on coupon dates when the bond is not callable.

[Election based lifecycling](#) on coupon dates when the bond is callable.

19.8.2.4 Inflation-Linked

There are different types of inflation-linked bonds in the marketplace. The [Inflation-linked bonds](#) currently supported in Daml Finance pay a fixed coupon rate at the end of every coupon period. This corresponds to the payoff of e.g. Treasury Inflation-Protected Securities (TIPS) that are issued by the U.S. Treasury. The coupon is calculated based on a principal that is adjusted according to an inflation index, for example the Consumer Price Index (CPI) in the U.S.

Here is an example of a bond paying 1.1% p.a. (on a CPI adjusted principal) with a 3M coupon period:

```

let
  issueDate = date 2019 Jan 16
  firstCouponDate = date 2019 Feb 15
  maturityDate = date 2019 May 15
  inflationIndexId = "CPI"
  notional = 1.0
  couponRate = 0.011
  couponPeriod = M
  couponPeriodMultiplier = 3
  dayCountConvention = Act365Fixed
  businessDayConvention = Following

```

Based on these terms we can create the inflation linked bond instrument:

```

let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
    exerciseCmd inflationLinkedBondFactoryCid InflationLinkedBondFactory.Create
  with
    inflationLinked = InflationLinked with
      instrument
      description
      periodicSchedule
      holidayCalendarIds
      calendarDataProvider
      dayCountConvention
      couponRate
      inflationIndexId
      inflationIndexBaseValue
      currency
      notional
      lastEventTimestamp
      observers = fromList observers

```

At maturity, the greater of the adjusted principal and the original principal is redeemed. For clarity, this only applies to the redemption amount. The coupons are always calculated based on the adjusted principal. This means that in the case of deflation, the coupons would be lower than the specified coupon rate but the original principal would still be redeemed at maturity.

19.8.2.5 Zero Coupon

A [zero coupon bond](#) does not pay any coupons at all. It only pays the redemption amount at maturity.

Here is an example of a zero coupon bond:

```

let
  issueDate = date 2019 Jan 16
  maturityDate = date 2020 May 15
  notional = 1000.0

```

Based on this we create the zero coupon bond instrument:

```

let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
    exerciseCmd zeroCouponBondFactoryCid ZeroCouponBondFactory.Create with
      zeroCoupon = ZeroCoupon with

```

(continues on next page)

(continued from previous page)

```
instrument
description
currency
issueDate
maturityDate
notional
lastEventTimestamp
observers = fromList observers
```

19.8.3 Frequently Asked Questions

19.8.3.1 How do I transfer or trade a bond?

When you have created a holding on a bond instrument this can be transferred to another party. This is described in the [Getting Started: Transfer](#) tutorial.

In order to trade a bond (transfer it in exchange for cash) you can also initiate a delivery versus payment with atomic settlement. This is described in the [Getting Started: Settlement](#) tutorial.

19.8.3.2 How do I process coupon payments for a bond?

On the coupon payment date, the issuer will need to lifecycle the bond. This will result in a lifecycle effect for the coupon, which can be cash settled. This is described in detail in the [Lifecycle](#) and the [Intermediated Lifecycle](#) tutorials.

19.8.3.3 How do I redeem a bond?

On the redemption date, both the last coupon and the redemption amount will be paid. This is processed in the same way as a single coupon payment described above.

19.8.3.4 How do I view the terms of a bond instrument?

There are several ways to access the data of a contract, as explained in the [Patterns](#) section.

19.9 Equity Instrument

To follow the code snippets used in this page in Daml Studio, you can [clone the Daml Finance repository](#) and run the scripts included in the [Instrument/Equity/Test/](#) folder.

19.9.1 How to use an Equity Instrument in your application

As explained in the [Getting Started](#) section and on the [Architecture](#) page, your app should only depend on the interface layer of Daml Finance. For equities this means that you should only include the [equity interface package](#).

Your initialization scripts are an exception, since they are only run once when your app is initialized. These are used to create the necessary instrument factories. Your app can then create equity instruments through these factory contracts.

19.9.2 The Equity Interface

The equity instrument supports different lifecycle events, such as dividends, stock splits and mergers. These are modeled using the choices on the [Equity interface](#), namely `DeclareDistribution`, `DeclareReplacement` and `DeclareStockSplit`. We will now demonstrate each one with a concrete lifecycle event.

19.9.3 Dividend

The most common lifecycle event of an equity is probably dividends. This normally means that the holder of a stock receives a given amount of cash for each stock held. This is modeled using the `DeclareDistribution` choice. It creates a [Distribution Event](#), which allows you to specify distribution per share. In the case of a cash dividend, this would be a cash instrument. However, the company can also choose to distribute additional stock or even stock options. Since the [Distribution Event](#) supports an arbitrary `perUnitDistribution` instrument, it can be used to model those use cases as well.

In order to process a lifecycle event, you have to create two versions of the instrument: one before the event and one after the event. In the case of a dividend event, this means one instrument *cum* dividend (which includes the dividend) and one *ex* dividend (which does no longer include the dividend):

```
cumEquityInstrument <-
  originateEquity issuer issuer "EQUITY-INST-1" "0" TransferableFungible "ABC"
--pp now
exEquityInstrument <-
  originateEquity issuer issuer "EQUITY-INST-1" "1" TransferableFungible "ABC"
--[] now
```

Once this is done, you can create a holding on it. This is not limited to integer holdings, but fractional holdings are supported as well:

```
-- Distribute holdings: fractional holdings are also supported.
investorEquityCid <- Account.credit [publicParty] cumEquityInstrument 1000.25
--investorAccount
```

We create a distribution rule for the cash dividend. It defines the business logic for the dividend and it has the issuer as signatory:

```
-- Create cash dividend rule
distributionRuleCid <- toInterfaceContractId @Lifecycle.I <$> submit issuer do
  createCmd Distribution.Rule with
```

(continues on next page)

(continued from previous page)

```

providers = Set.singleton issuer
lifecyclel = issuer
observers = Set.singleton publicParty
id = Id "LifecycleRule"
description = "Rule to lifecycle an instrument following a distribution"
event"

```

We also need a distribution event, which defines the terms of the dividend. In this case, it is USD 2 cash per share (this also works for a fractional amount of shares):

```

-- Create cash dividend event: USD 2 per share (this also works with fractional
shares)
distributionEventCid <-
  Instrument.submitExerciseInterfaceByKeyCmd @Equity.I [issuer] []
cumEquityInstrument
  Equity.DeclareDistribution with
    id = Id $ "ABC - " <> show now
    description = "Cash Dividend"
    effectiveTime = now
    newInstrument = exEquityInstrument
    perUnitDistribution = [qty 2.0 cashInstrument]

```

This allows the issuer to lifecycle the instrument by exercising the `Evolve` choice:

```

-- Lifecycle cash dividend
(, [effectCid]) <- submit issuer do
  exerciseCmd distributionRuleCid Lifecycle.Evolve with
    observableCids = []
    eventCid = distributionEventCid
    instrument = cumEquityInstrument

```

This results in a lifecycle effect, which can be settled. The settlement of effects is covered in the [Lifecycleing tutorial](#).

19.9.4 Bonus issue

Instead of a cash dividend, a company may also decide to offer free shares (or warrants) instead of cash to current shareholders. This is called *bonus issue* and it is modeled in a similar way to the dividend above. The main difference is in the distribution event, which now distributes a different instrument (equity instead of cash):

```

-- Create bonus issue event: receive 2 additional shares for each share
currently held
-- (this also works with fractional shares)
distributionEventCid <-
  Instrument.submitExerciseInterfaceByKeyCmd @Equity.I [issuer] []
cumEquityInstrument
  Equity.DeclareDistribution with
    id = Id $ "ABC - " <> show now
    description = "Bonus issue"
    effectiveTime = now
    newInstrument = exEquityInstrument
    perUnitDistribution = [qty 2.0 exEquityInstrument]

```

Similarly, if there is a bonus issue that awards warrants instead of equity, that can be modeled in the same way. Just replace the equity instrument by a warrant instrument on the `perUnitDistribution` line above.

19.9.5 Dividend option

A company may give shareholders the option of choosing what kind of dividend they want to receive. For example, a shareholder could choose between a dividend in cash or in stock. Currently, there are two different ways this can be modeled in the library:

19.9.5.1 1. Using a dividend option instrument

The preferred way is to model this using the following two components:

A dividend option instrument, which describes the economic terms of the rights a shareholder receives. The page on the [Option Instrument package](#) describes how to create a physically settled [Dividend](#) option.

The `DeclareDistribution` choice to distribute the above option instrument in the correct proportion (e.g. 1 option contract for each share held). This can be done in the same way as the [Bonus Issue](#) example described earlier, just change the `perUnitDistribution` line to distribute the option instrument you created above.

When current shareholders receive the option instrument they can choose between one of the dividend payment types offered by the issuer, for example cash in a foreign currency.

More details on this dividend option process are described in [Instrument/Equity/Test/DivOption.daml](#), in particular how to define and process an *Election*.

19.9.5.2 2. Using multiple distribution events

The `DeclareDistribution` choice can be used for this as well. The issuer creates one event for each dividend option that shareholders can choose from:

```
-- Create dividend option event.
-- For each share currently held, the shareholder can choose to either receive
↪ cash (USD 10.5) or
-- stock (1.5 additional shares).
-- perUnitDistribution is an arbitrary list, so this can be extended with
↪ additional options, e.g.
-- warrants or cash in a different currency.
distributionEventCashCid <-
  Instrument.submitExerciseInterfaceByKeyCmd @Equity.I [issuer] []
↪ cumEquityInstrument
  Equity.DeclareDistribution with
    id = Id $ "ABC - " <> show now
    description = "Dividend option: cash"
    effectiveTime = now
    newInstrument = exEquityInstrument
    perUnitDistribution = [qty 10.5 cashInstrument]

distributionEventStockCid <-
  Instrument.submitExerciseInterfaceByKeyCmd @Equity.I [issuer] []
↪ cumEquityInstrument
```

(continues on next page)

(continued from previous page)

```

Equity.DeclareDistribution with
  id = Id $ "ABC - " <> show now
  description = "Dividend option: stock"
  effectiveTime = now
  newInstrument = exEquityInstrument
  perUnitDistribution = [qty 1.5 exEquityInstrument]

```

The issuer then lifecycles each event individually, to generate two alternative lifecycling effects:

```

-- Lifecycle dividend option
(⟦, [effectCashCid]) <- submit issuer do
  exerciseCmd distributionRuleCid Lifecycle.Evolve with
    observableCids = []
    eventCid = distributionEventCashCid
    instrument = cumEquityInstrument

(⟦, [effectStockCid]) <- submit issuer do
  exerciseCmd distributionRuleCid Lifecycle.Evolve with
    observableCids = []
    eventCid = distributionEventStockCid
    instrument = cumEquityInstrument

```

The investor can then claim one or the other:

```

-- The investor chooses the stock dividend
result <- submitMulti [investor] [publicParty] do
  exerciseCmd claimRuleCid Claim.ClaimEffect with
    claimer = investor
    holdingCids = [investorEquityCid]
    effectCid = effectStockCid
    batchId = Id "DividendOptionSettlement"

```

When this is settled, the investor's holding is consumed, which prevents the investor from receiving more than one of the dividend options.

19.9.6 Rights Issue

In order to raise money, a company may decide to issue new shares and give current shareholders the right (but not the obligation) to purchase those additional shares at a discounted price. This can be modeled using two components:

An option instrument, which describes the economic terms of the rights a shareholder receives. For example, this could be a European option with a strike price below the current spot price, and a maturity three weeks in the future. The page on the [Option Instrument package](#) describes how to create a physically settled European option.

The `DeclareDistribution` choice to distribute the above option instrument in the correct proportion (e.g. 3 option contracts for each 10 shares held). This can be done in the same way as the Bonus Issue example described earlier, just change the `perUnitDistribution` line to distribute the option instrument you created above.

When current shareholders receive the option instrument they can typically choose between:

1. Exercising the option. This corresponds to a Rights Subscription (described in more detail in the next section below).

2. Choosing not to exercise the option. The option will expire worthless.
3. Selling the option. This is not always possible, it depends on the terms of the rights issue.
[Getting Started: Settlement](#) describes how this could be done.

19.9.7 Rights Subscription

Investors that decide to purchase those additional shares (subscribe to the stock issuance) can elect to exercise their right (a call option), either in parts or in whole. Sometimes, it is also possible to apply for excess subscription. For example, an investor would like to subscribe for 150 shares but has regular rights for only 100 shares. In that case, the investor would:

Exercise the call option in whole to subscribe for the guaranteed part (100 shares).

Write a put option for the excess part (50 shares). The issuer could then exercise this in part or in whole.

More details on the Rights Issue and Subscription process are described in [Instrument/Equity/Test/RightsIssue.daml](#), in particular how to define and process an *Election*.

19.9.8 Stock split

A stock split is when a company increases its number of shares. For example, a 2-for-1 stock split means that a shareholder will have two shares after the split for every share held before the split. This is modeled using the `DeclareStockSplit` choice, which has an `adjustmentFactor` argument.

The `DeclareStockSplit` choice creates a [Replacement Event](#), which allows you to replace units of an instrument with another instrument (or a basket of other instruments). Consequently, this interface can also be used for other types of corporate actions (for example, see the *merger* scenario below).

The workflow for a stock split is quite similar to that of a dividend above. We start by defining the instrument before and after the lifecycle event:

```
preEquityInstrument <-
  originateEquity issuer issuer "INST-1" "0" TransferableFungible "AAPL" pp now
postEquityInstrument <-
  originateEquity issuer issuer "INST-1" "1" TransferableFungible "AAPL" [] now
```

We create a replacement rule for the stock split:

```
-- Create lifecycle rule
replacementRuleCid <- toInterfaceContractId @Lifecycle.I <$> submit issuer do
  createCmd Replacement.Rule with
    providers = Set.singleton issuer
    lifecycler = issuer
    observers = Set.singleton publicParty
    id = Id "LifecycleRule"
    description = "Rule to lifecycle an instrument following a replacement event"
  =>
```

We also need a replacement event. For a 2-for-1 stock split, the `adjustmentFactor` is $1/2 = 0.5$:

```
-- Create stock split event
replacementEventCid <-
  Instrument.submitExerciseInterfaceByKeyCmd @Equity.I [issuer] []
  => preEquityInstrument
```

(continues on next page)

(continued from previous page)

```

Equity.DeclareStockSplit with
  id = Id $ "APPL - " <> show now
  description = "Stocksplit"
  effectiveTime = now
  newInstrument = postEquityInstrument
  adjustmentFactor = 0.5

```

This allows the issuer to lifecycle the instrument:

```

-- Lifecycle stock split
(, [effectCid]) <- submit issuer do
  exerciseCmd replacementRuleCid Lifecycle.Evolve with
    observableCids = []
    eventCid = replacementEventCid
    instrument = preEquityInstrument

```

This results in a lifecycle effect, which can be settled (similar to the *dividend* scenario above).

19.9.8.1 Reverse Stock Split

The stock split described above increases the number of shares available. Alternatively, a company may also decide to *decrease* the number of shares. This is referred to as *reverse stock split* or *stock consolidation*.

The `DeclareStockSplit` choice supports this as well. For example, for a 1-for-10 reverse split, modify the `adjustmentFactor` to $10/1 = 10.0$ in the example above.

19.9.9 Merger

The merger scenario models the case when one company acquires another company and pays for it using its own shares. This is modeled using the `DeclareReplacement` choice, which also uses the [Replacement Event](#) (like the stock split scenario above). This is a mandatory exchange offer: no election is required (or possible) by the shareholder.

We start by defining the instrument before and after the merger. Shares of company ABC are being replaced by shares of company XYZ:

```

mergingInstrument <-
  originateEquity merging merging "INST-1" "0" TransferableFungible "ABC" pp now
mergedInstrument <-
  originateEquity merged merged "INST-2" "0" TransferableFungible "XYZ" pp now

```

We create a replacement rule for the merger:

```

-- Create lifecycle rules
replacementRuleCid <- toInterfaceContractId @Lifecycle.I <$> submit merging do
  createCmd Replacement.Rule with
    providers = Set.singleton merging
    lifecycler = merging
    observers = Set.singleton publicParty
    id = Id "LifecycleRule"
    description = "Rule to lifecycle an instrument following a replacement event"
  <-

```

We also need a replacement event. Two shares of ABC are replaced by one share of XYZ, so the factor used in `perUnitReplacement` is 0.5:

```
-- Create replacement event
-- perUnitReplacement is an arbitrary list of instruments, so the investor can
also receive a
-- combination of shares and cash.
replacementEventCid <-
  Instrument.submitExerciseInterfaceByKeyCmd @Equity.I [merging] []
mergingInstrument
  Equity.DeclareReplacement with
    id = Id $ "ABC merge - " <> show now
    description = "Merge"
    effectiveTime = now
    perUnitReplacement = [qty 0.5 mergedInstrument]
```

This allows the issuer to lifecycle the instrument:

```
-- Lifecycle replacement event
(_, [effectCid]) <- submit merging do
  exerciseCmd replacementRuleCid Lifecycle.Evolve with
    eventCid = replacementEventCid
    observableCids = []
    instrument = mergingInstrument
```

This results in a lifecycle effect, which can be settled as usual.

19.9.10 Frequently Asked Questions

19.9.10.1 How do I transfer or trade an Equity?

When you have created a holding on an Equity instrument this can be transferred to another party. This is described in the [Getting Started: Transfer](#) tutorial.

In order to trade an Equity (transfer it in exchange for cash) you can also initiate a delivery versus payment with atomic settlement. This is described in the [Getting Started: Settlement](#) tutorial.

19.9.10.2 How do I process dividend payments for an Equity?

On the dividend payment date, the issuer will need to lifecycle the Equity. This will result in a lifecycle effect for the dividend, which can be cash settled. This is described in detail in the [Lifecycling](#) and the [Intermediated Lifecycling](#) tutorials (depending on what kind of settlement you need).

19.10 Option Instrument

To follow the script used in this tutorial, you can [clone the Daml Finance repository](#). In particular, the Option test folder [Instrument/Option/Test/](#) is the starting point of this tutorial.

19.10.1 How To Create an Option Instrument

In order to create an option instrument, you first have to decide what type of option you need. The [option extension package](#) currently supports the following types of options:

19.10.1.1 European Options

European options give the holder the right, but not the obligation, to buy (in case of a *call*) or to sell (in case of a *put*) the underlying asset at predetermined *strike* price on a specific *expiry* date in the future.

Daml Finance supports two types of European Options:

Physically settled European Option

The [EuropeanPhysical](#) instrument models physically settled call or put options.

There are two important characteristics of this instrument:

1. *physical settlement*: option holders that choose to exercise will buy (in case of a *call*) or sell (in case of a *put*) the underlying asset at the predetermined *strike* price. Since this option instrument is physically settled, it means that the underlying asset will change hands.
2. *manual exercise*: This option instrument is not automatically exercised. Instead, the option holder must manually decide whether or not to exercise. This is done by making an *Election*.

As an example, consider an option instrument that gives the holder the right to buy AAPL stock at a given price. This example is taken from [Instrument/Option/Test/EuropeanPhysical.daml](#), where all the details are available. Also, Check out the [Election based lifecycling tutorial](#) for more details on how how to define and process an *Election* in practice.

You start by defining the terms:

```
strike = 50.0
expiryDate = date 2019 May 15
```

Now that the terms have been defined, you can create the option instrument:

```

let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
    exerciseCmd europeanPhysicalOptionFactoryCid EuropeanPhysicalOptionFactory.
  ↪ Create with
    european = EuropeanPhysicalOption.European with
      instrument
      description
      expiryDate
      optionType
      strike
      referenceAsset
      ownerReceives
      currency
      lastEventTimestamp
      prevEvents = []
      observers = Map.fromList observers

```

Once this is done, you can create a holding on it using [Account.Credit](#).

Cash-settled European Option

The [EuropeanCash](#) instrument models cash-settled, auto-exercising call or put options. They are similar to the [EuropeanPhysical](#) instrument described above, but there are two important differences:

1. *cash settlement*: This means that the underlying asset will not change hands. Instead, a cash settlement will take place (if the option is exercised).
2. *automatic exercise*: This option instrument is automatically exercised. No manual *Election* is required by the holder.

As an example, consider an option instrument that gives the holder the right to buy AAPL stock at a given price. This example is taken from [Instrument/Option/Test/EuropeanCash.daml](#), where all the details are available.

You start by defining the terms:

```

strike = 50.0
expiryDate = date 2019 May 15
referenceAssetId = "AAPL-CLOSE"

```

Now that the terms have been defined, you can create the option instrument:

```

let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

```

(continues on next page)

(continued from previous page)

```

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd europeanCashOptionFactoryCid EuropeanCashOptionFactory.Create
  ↪with
    european = EuropeanCashOption.European with
      instrument
      description
      expiryDate
      optionType
      strike
      referenceAssetId
      ownerReceives
      currency
      lastEventTimestamp
    observers = Map.fromList observers

```

Once this is done, you can create a holding on it using [Account.Credit](#).

If the close price of AAPL on the expiry date is above the *strike* price, the option holder would profit from exercising the option and buying the stock at the strike price. The value of the option would be *spot - strike*. Since this option type is cash-settled, this amount would be paid in the option currency after lifecycling.

On the other hand, if the close price of AAPL is below the *strike* price, the option would expire worthless.

This option instrument is automatically exercised. This means that the decision whether or not to exercise is done automatically by comparing the *strike* price to an observation of the close price. For this to work, you need to define an *Observation* as well:

```

let observations = Map.fromList [(dateToDateClockTime $ date 2019 May 15, 48.
  ↪78)]
observableCid <- toInterfaceContractId <$> submit issuer do
  createCmd Observation with
    provider = issuer; id = Id referenceAssetId; observations; observers =
  ↪mempty

```

19.10.1.2 Barrier Option

The [BarrierEuropeanCash](#) instrument models barrier options. They are similar to the [EuropeanCash](#) instrument described above, but also contain a barrier that is used to activate (or, alternatively, knock out) the option. The [BarrierTypeEnum](#) describes which barrier types are supported.

As an example, consider an option instrument that gives the holder the right to buy AAPL stock at a given price. However, if AAPL ever trades at or below a given barrier level, the option is knocked out (which means that it expires worthless). In other words, this describes a [DownAndOut](#) option. This example is taken from [Instrument/Option/Test/BarrierEuropeanCash.daml](#), where all the details are available.

You start by defining the terms:

```

barrier = 30.0
barrierType = DownAndOut
barrierStartDate = date 2019 Jan 20
strike = 40.0

```

(continues on next page)

(continued from previous page)

```
expiryDate = date 2019 May 15
referenceAssetId = "AAPL-CLOSE"
```

Now that the terms have been defined, you can create the option instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
    exerciseCmd barrierOptionFactoryCid BarrierEuropeanCashOptionFactory.Create
  with
    barrierEuropean = BarrierEuropean with
      instrument
      description
      expiryDate
      optionType
      strike
      barrier
      barrierType
      barrierStartDate
      referenceAssetId
      ownerReceives
      currency
      lastEventTimestamp
      observers = Map.fromList observers
```

Once this is done, you can create a holding on it using [Account.Credit](#).

Compared to the [EuropeanCash option](#) this instrument needs to be lifecycled not only at expiry but also during its lifetime in case of a barrier hit. This is done in the same way as lifecycling at maturity, i.e. an *Observation* is provided for the reference asset identifier, containing the date and the underlying price.

19.10.1.3 Dividend Option

The [Dividend](#) instrument models physically settled, manually exercised dividend options. For reference, a dividend option gives the holder the right to choose one out of several dividend payouts, on a specific expiry date in the future. The following payout types are supported:

1. **Cash:** The dividend is paid in cash. This a mandatory option. In addition, the issue can offer:
2. **Shares:** The dividend is paid in shares. To the investor this is similar to a [Bonus Issue](#).
3. **CashFx:** The dividend is paid in cash in a foreign currency.

As an example, consider an option instrument that gives the holder the right to choose to receive AAPL dividends either as cash, shares or cash in a foreign currency (EUR). This example is taken from [Instrument/Option/Test/Dividend.daml](#), where all the details are available.

You start by defining the terms:

```
expiryDate = date 2019 May 15
cashQuantity = qty 0.19 cashInstrument
sharesQuantity = Some $ qty 0.0041 aaplInstrument
fxQuantity = Some $ qty 0.17 eurInstrument
```

Now that the terms have been defined, you can create the option instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd dividendOptionFactoryCid DividendOption.Create with
    dividend = Dividend with
      instrument
      description
      expiryDate
      cashQuantity
      sharesQuantity
      fxQuantity
      lastEventTimestamp
      prevEvents = []
    observers = Map.fromList observers
```

Once this is done, you can create a holding on it using [Account.Credit](#).

On the expiry date, the option holder will make an *Election* out of the available choices. The lifecycling of this option works in the same way as for [physically settled European options](#).

19.10.2 Frequently Asked Questions

19.10.2.1 How do I transfer or trade an option?

When you have created a holding on an option instrument this can be transferred to another party. This is described in the [Getting Started: Transfer](#) tutorial.

In order to trade an option (transfer it in exchange for cash) you can also initiate a delivery versus payment with atomic settlement. This is described in the [Getting Started: Settlement](#) tutorial.

19.10.2.2 How do I calculate settlement payments for an option?

On the expiry date, the issuer will need to lifecycle the European option. This will result in a lifecycle effect for the payoff, which can be cash settled. This is described in detail in the [Lifecycling](#) and the [Intermediated Lifecycling](#) tutorials.

19.11 Structured Product

To follow the script used in this tutorial, you can [clone the Daml Finance repository](#). In particular, the Structured Product test folder `Instrument/StructuredProduct/Test/` is the starting point of this tutorial.

19.11.1 How to create a Structured Product Instrument

In order to create a structured product instrument, you first have to decide what type of payoff you need. The [structured product instrument packages](#) currently supports the following types of payoffs:

19.11.1.1 Barrier Reverse Convertible

The `BarrierReverseConvertible` instrument models cash-settled, auto-exercising barrier reverse convertible (BRC) instruments. It can be seen as a long fixed coupon bond and a short Down-And-In put option.

For example, consider a BRC that pays a fixed 5% coupon rate and has a barrier level of 30 USD. If the underlying ever trades below this level, the put option is knocked in (activated). This would reduce the redemption amount if the underlying closes below the strike price at expiry.

This example is taken from the [BarrierReverseConvertible.daml test file](#), where all the details are available.

You start by defining the terms:

```
barrier = 30.0
barrierStartDate = date 2019 Jan 16
strike = 40.0
expiryDate = date 2019 May 15
referenceAssetId = "AAPL-CLOSE"
couponRate = 0.05
issueDate = date 2019 Jan 16
firstCouponDate = date 2019 Feb 15
maturityDate = date 2019 May 15
```

Now that the terms have been defined, you can create the BRC instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd brcFactoryCid BarrierReverseConvertibleFactory.Create with
    barrierReverseConvertible = BarrierReverseConvertible with
      instrument
      description
      expiryDate
      strike
```

(continues on next page)

(continued from previous page)

```

    barrier
    barrierStartDate
    referenceAssetId
    couponRate
    periodicSchedule
    holidayCalendarIds
    calendarDataProvider
    dayCountConvention
    notional
    currency
    lastEventTimestamp
    prevEvents = []
    observers = Map.fromList observers

```

Once this is done, you can create a holding on it using [Account.Credit](#).

This BRC instrument is automatically exercised. This means that the decision whether or not to exercise the embedded option is done automatically by comparing observations of the underlying to the *strike* and *barrier* level of the instrument. For this to work, you need to define an *Observation* as well:

```

let
  observations = Map.fromList
    [ (dateToDataClockTime $ date 2019 Feb 13, 28.78)
    , (dateToDataClockTime $ date 2019 Feb 15, 39.78)
    , (dateToDataClockTime $ date 2019 May 15, 38.78)
    , (dateToDataClockTime $ date 2019 May 16, 18.78)
    , (dateToDataClockTime $ date 2019 May 17, 38.78)
    ]
  observableCid <- toInterfaceContractId <$> submit issuer do
    createCmd Observation with
      provider = issuer; id = Id referenceAssetId; observations; observers = []
  ↪empty

```

Since this option instrument is cash-settled, the underlying asset will not change hands. Instead, the cash value of the payoff is paid to the BRC holder.

19.11.1.2 Auto-Callable

The [AutoCallable](#) instrument models a single-underlying auto-callable note that pays a conditional coupon.

Coupon payment

The conditional coupon is paid in every period unless the *coupon barrier* is hit at the end of the period. There is no coupon memory – coupons missed due to barrier hits are not repaid in future periods.

Early redemption

If the underlying asset closes above the *call barrier* on an observation date, the instrument is automatically redeemed early at the end of that period.

Redemption at maturity (if not redeemed early)

At maturity, the principal amount is repaid unless a *final barrier* has been breached on the last observation date (in which case the performance of the underlying asset is paid). In other words, this instrument models an AutoCallable Barrier Reverse Convertible where the knock-in put is struck at 100% and the barrier is observed at maturity.

Example

For example, consider an auto-callable yield note that pays a conditional 5% coupon. (For more details, see the [AutoCallable.daml test file](#) for this example.)

Start by defining the terms:

```
putStrike = 1.00 -- 100% of the underlying closing price on the initial
↪fixing date
couponBarrier = 0.65 -- 65% of the underlying closing price on the initial
↪fixing date
callBarrier = 1.00
finalBarrier = 0.875
referenceAssetId = "AAPL-CLOSE"
couponRate = 0.05
dayCountConvention = Basis1 -- coupon rate is paid each period, not per annum.
businessDayConvention = Following
couponPeriod = M
couponPeriodMultiplier = 3
initialFixingDate = date 2024 Jan 10
issueDate = date 2024 Jan 16
firstRegularObservationDate = date 2024 Mar 28
firstCouponDate = date 2024 Apr 2
secondCouponDate = date 2024 Jul 2
expiryDate = date 2024 Sep 28
maturityDate = date 2024 Oct 2
```

Note that the *Basis1* day-count convention specifies that the 5% coupon is paid in every coupon period (not per annum).

Now that the terms have been defined, you can create the AutoCallable instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
```

(continues on next page)

(continued from previous page)

```
exerciseCmd factoryCid AutoCallableFactory.Create with
  autoCallable = AutoCallable with
    instrument
    description
    putStrike
    couponBarrier
    callBarrier
    finalBarrier
    referenceAssetId
    couponRate
    observationSchedule
    periodicSchedule
    holidayCalendarIds
    calendarDataProvider
    dayCountConvention
    notional
    currency
    lastEventTimestamp
    prevEvents = []
    observers = Map.fromList observers
```

Then you can create a holding on it using [Account.Credit](#).

This instrument is automatically called. This means that the decision whether or not to exercise the embedded option is done automatically using the observations of the underlying asset.

Because this option instrument is cash-settled, the underlying asset does not change hands. Instead, the cash value of the payoff is paid to the holder.

19.11.2 Frequently Asked Questions

19.11.2.1 How do I calculate settlement payments for a structured product?

Similar to a fixed coupon bond, a BRC instrument needs to be lifecycled on the coupon dates and at expiry, in order to calculate the corresponding payments. This is described in the [Lifecycling](#) tutorial. In addition, if the instrument has a barrier (which is the case for a BRC), it needs to be lifecycled regularly during its lifetime to record any barrier breach, which would impact the redemption payment.

19.12 Swap Instrument

To follow the code snippets used in this page in Daml Studio, you can [clone the Daml Finance repository](#) and run the scripts included in the [Instrument/Swap/Test/](#) folder.

19.12.1 Prerequisites

Swap instruments share many similarities with Bond instruments. This page builds on the page for the [Bond Instruments](#). Please, check it out before reading the Swap specifics below.

19.12.2 How To Create a Swap Instrument

There are different types of swaps, which differ both in the way regular payments are defined and whether notional is exchanged. In order to create a swap instrument, you first have to decide what type of swap you need. The [swap instrument package](#) currently supports the following types of swaps:

19.12.2.1 Interest Rate

[Interest rate swap](#) is the type of swap that shares most similarities with a bond. It has two legs: one which pays a fix rate and another one which pays a floating rate. These rates are paid at the end of every payment period.

As an example, we will create a swap instrument paying Libor 3M vs a 2.01% p.a. with a 3M payment period. This example is taken from [Instrument/Swap/Test/InterestRate.daml](#), where all the details are available.

We start by defining the terms:

```
let
  issueDate = date 2019 Jan 16
  firstPaymentDate = date 2019 Feb 15
  maturityDate = date 2019 May 15
  referenceRateId = "USD/LIBOR/3M"
  floatingRate = FloatingRate with
    referenceRateId
    referenceRateType = SingleFixing CalculationPeriodStartDate
    fixingDates = DateOffset with
      periodMultiplier = 0
      period = D
      dayType = Some Business
      businessDayConvention = NoAdjustment
      businessCenters = ["USD"]
  ownerReceivesFix = False
  fixRate = 0.0201
  paymentPeriod = M
  paymentPeriodMultiplier = 3
  dayCountConvention = Act360
  businessDayConvention = ModifiedFollowing
```

The floating leg depends on a reference rate, which is specified in the [FloatingRate](#) data structure. It supports two types of reference rates, which are configurable using the [ReferenceRateTypeEnum](#):

Libor/Euribor style rates with a single fixing

SOFR style reference rates (using a compounded index)

The `ownerReceivesFix` variable is used to specify whether a holding owner of this instrument receives the fix or the floating leg. This is not needed for bonds, because the regular payments are always in one direction (from the issuer to the holder). However, in the case of a swap with two counterparties A and B, we need the `ownerReceivesFix` variable to specify who receives fix and who receives floating. In this example, the holding owner receives the floating leg.

Just as for bonds, we can use these variables to create a [PeriodicSchedule](#):

```
let
  (y, m, d) = toGregorian firstCouponDate
  periodicSchedule = PeriodicSchedule with
    businessDayAdjustment =
      BusinessDayAdjustment with
        calendarIds = holidayCalendarIds
        convention = businessDayConvention
    effectiveDateBusinessDayAdjustment = None
    terminationDateBusinessDayAdjustment = None
    frequency =
      Periodic Frequency with
        rollConvention = DOM d
        period = Period with
          period = couponPeriod
          periodMultiplier = couponPeriodMultiplier
    effectiveDate = issueDate
    firstRegularPeriodStartDate = Some firstCouponDate
    lastRegularPeriodEndDate = Some maturityDate
    stubPeriodType = None
    terminationDate = maturityDate
```

For more information on calendar, schedule, and day count functions, see the [date utility functions tutorial](#).

Note that this instrument only has one periodic schedule, which is used for both the fixed and the floating leg. It is also used for both the calculation period (to determine which floating rate to be used) and the payment period (to determine when payments are done). The [FpML swap template](#) below offers more flexibility here. It has individual schedules, both for the fixed/floating leg and for the calculation/payment periods. That would allow you to specify whether payments should be made e.g. after each calculation period or only after every second calculation period.

Now that we have defined the terms we can create the swap instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
    exerciseCmd interestRateSwapFactoryCid InterestRateSwapFactory.Create with
      interestRate = InterestRate with
        instrument
        description
        periodicSchedule
```

(continues on next page)

(continued from previous page)

```

holidayCalendarIds
calendarDataProvider
dayCountConvention
floatingRate
fixRate
ownerReceivesFix
currency
lastEventTimestamp
observers = fromList observers

```

Once this is done, you can create a holding on it using [Account.Credit](#). The owner of the holding receives the floating leg (and pays the fix leg).

19.12.2.2 Currency

[Currency swaps](#) are quite similar to interest rate swaps, except that the two legs are in different currencies. Consequently, we need to create two cash instruments:

```

cashInstrument <- originate custodian issuer "USD" TransferableFungible "USD"
↳ "Dollars" observers now
foreignCashInstrument <- originate custodian issuer "EUR" TransferableFungible
↳ "Euro" observers
now

```

In the swap template they are referred to as *base currency* and *foreign currency*.

Here is an example of a fix vs fix currency swap: 3% p.a. in USD vs 2% p.a. in EUR with payments every 3M:

```

let
  issueDate = date 2019 Jan 16
  firstPaymentDate = date 2019 Feb 15
  maturityDate = date 2019 May 15
  ownerReceivesBase = False
  baseRate = 0.03
  foreignRate = 0.02
  fxRate = 1.1
  paymentPeriod = M
  paymentPeriodMultiplier = 3
  dayCountConvention = Act360
  businessDayConvention = ModifiedFollowing

```

In this example, the holding owner receives the foreign currency leg.

In order to calculate the interest rate payments, a notional is required in each currency. The quantity of the holding refers to the notional of the base currency. The notional of the foreign currency is defined as the quantity of the holding multiplied by the specified *fxRate*.

Note that this template is limited to fixed rates. It also does not support exchange of notionals. If you need floating rates or exchange of notionals, please use the [FpML swap template](#) below. It supports both of those features.

Here is how we create the currency swap instrument, using the two currencies defined above:

```

let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd currencySwapFactoryCid CurrencySwapFactory.Create with
    currencySwap = CurrencySwap with
      instrument
      description
      periodicSchedule
      holidayCalendarIds
      calendarDataProvider
      dayCountConvention
      ownerReceivesBase
      baseRate
      foreignRate
      baseCurrency
      foreignCurrency
      fxRate
      lastEventTimestamp
    observers = fromList observers

```

Once the instrument is created, you can create a holding on it. In our example, it the owner of the holding receives the foreign currency leg (and pays the base currency leg).

19.12.2.3 Foreign Exchange

Despite the similarities in name, *foreign exchange swaps* (or FX swaps) are quite different from currency swaps. An FX swap does not pay or receive interest. Instead, the two legs define an initial FX transaction and a final FX transaction. Each transaction requires an FX rate and a transaction date, which are predetermined between the counterparties.

The FX transactions involve two currencies. In the swap template these are referred to as *base currency* and *foreign currency*. The convention is that the holding owner receives the foreign currency in the initial transaction (and pays it in the final transaction).

Here is an example of an USD vs EUR FX swap. First, we define the two cash instruments:

```

cashInstrument <- originate custodian issuer "USD" TransferableFungible "USD"
↳ "Dollars" observers now
foreignCashInstrument <- originate custodian issuer "EUR" TransferableFungible
↳ "Euro" observers
now

```

Then, we define the transaction dates and FX rates:

```

let
  issueDate = date 2019 Jan 16
  firstPaymentDate = date 2019 Feb 15
  maturityDate = date 2019 May 15

```

(continues on next page)

(continued from previous page)

```
firstFxRate = 1.1
finalFxRate = 1.2
```

The *firstPaymentDate* variable defines the date of the initial FX transaction. Generally, this is on the issue date or shortly afterwards.

Finally, we create the FX swap instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
    exerciseCmd foreignExchangeSwapFactoryCid ForeignExchangeSwapFactory.Create
  with
    foreignExchange = ForeignExchange with
      instrument
      description
      baseCurrency
      foreignCurrency
      firstFxRate
      finalFxRate
      issueDate
      firstPaymentDate
      maturityDate
      lastEventTimestamp
      observers = fromList observers
```

Once the instrument is created, you can create a holding on it. The owner of the holding receives the foreign currency in the initial transaction. In the final transaction the sides are reversed.

19.12.2.4 Credit Default

A *credit default swap* (CDS) pays a protection amount in case of a credit default event, in exchange for a fix rate at the end of every payment period. The protection amount is defined as $1 - \text{recoveryRate}$. The *recoveryRate* is defined as the amount recovered when a borrower defaults, expressed as a percentage of notional.

If a credit event occurs, the swap expires after the protection amount has been paid, i.e., no more rate payments are required afterwards.

Here is an example of a CDS that pays $1 - \text{recoveryRate}$ in the case of a default on TSLA bonds:

```
issueDate = date 2019 Jan 16
firstPaymentDate = date 2019 Feb 15
maturityDate = date 2019 May 15
defaultProbabilityReferenceId = "TSLA-DEFAULT-PROB"
recoveryRateReferenceId = "TSLA-RECOVERY-RATE"
ownerReceivesFix = False
fixRate = 0.0201
```

(continues on next page)

(continued from previous page)

```

paymentPeriod = M
paymentPeriodMultiplier = 3
dayCountConvention = Act360
businessDayConvention = ModifiedFollowing

```

In our example, the issuer pays the protection leg of the swap.

As you can see in this example, two observables are required for a CDS:

1. `defaultProbabilityReferenceId`: The reference ID of the default probability observable. For example, in case of protection against a TSLA bond payment default this should be a valid reference to the TSLA default probability .
2. `recoveryRateReferenceId`: The reference ID of the recovery rate observable. For example, in case of a TSLA bond payment default with a 60% recovery rate this should be a valid reference to the TSLA bond recovery rate .

Finally, we create the CDS instrument:

```

let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd creditDefaultSwapFactoryCid CreditDefaultSwapFactory.Create with
    creditDefault = CreditDefault with
      instrument
      description
      periodicSchedule
      holidayCalendarIds
      calendarDataProvider
      dayCountConvention
      fixRate
      ownerReceivesFix
      defaultProbabilityReferenceId
      recoveryRateReferenceId
      currency
      lastEventTimestamp
    observers = fromList observers

```

Once the instrument is created, you can create a holding on it. In our example, the owner of the holding receives the protection leg (and pays the fix leg).

19.12.2.5 Asset

An [asset swap](#) is a general type of swap with two legs: one which pays an interest rate and another one which pays the performance of an asset (or a basket of assets). It can be used to model:

- equity swaps
- some types of commodity swaps (of the form *performance vs rate*)
- other swaps with the same payoff on other asset types.

Here is an example of an asset swap that pays AAPL total return vs 2.01% fix p.a., payment every 3M:

```
let
  issueDate = date 2019 Jan 16
  firstPaymentDate = date 2019 Feb 15
  maturityDate = date 2019 May 15
  referenceAssetId = "AAPL-CLOSE-ADJ"
  ownerReceivesFix = False
  floatingRate = None
  fixRate = 0.0201
  paymentPeriod = M
  paymentPeriodMultiplier = 3
  dayCountConvention = Act360
  businessDayConvention = ModifiedFollowing
```

In our example, the issuer pays the asset leg of the swap.

Finally, we create the asset swap instrument:

```
let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

cid <- submitMulti [issuer] [publicParty] do
  exerciseCmd assetSwapFactoryCid AssetSwapFactory.Create with
    asset = Asset with
      instrument
      description
      periodicSchedule
      holidayCalendarIds
      calendarDataProvider
      dayCountConvention
      floatingRate
      fixRate
      ownerReceivesRate
      underlyings
      currency
      lastEventTimestamp
    observers = fromList observers
```

Once this is done, you can create a holding on it. The owner of the holding receives the asset leg (and pays the fix leg).

One observable is required: *referenceAssetId*. The template calculates the performance for each payment period using this observable. Performance is calculated from the start date to the end date

of each payment period. The reference asset Observable needs to contain the appropriate type of fixings:

unadjusted fixings in case of a *price return* asset swap
adjusted fixings in case of a *total return* asset swap

There is one exception to this: a *total return* asset swap with *dividend passthrough*. In this case, you can use *unadjusted* fixings for the instrument and lifecycle the dividend event separately using a dedicated asset swap *DistributionRule*:

```
-- Lifecycle the asset swap to create an effect for the dividend.
(Some swapInstrumentAfterDividend, [effectCid]) <- submitMulti [issuer]
[publicParty] do
  exerciseCmd distributionRuleCid Lifecycle.Evolve with
    observableCids = []
    eventCid = aaplDividendDistributionEventCid
    instrument = swapInstrumentAfterFirstPayment
```

19.12.2.6 FpML

Unlike the other swap types above, the *FpML swap* template is not a new type of payoff. Instead, it allows you to input other types of swaps using the *FpML schema*. Currently, interest rate swaps and currency swaps are supported. The template can quite easily be extended to FX swaps.

Specifically, it allows you to specify one *swapStream* object for each leg of the swap.

We start by defining the general terms:

```
let
  issueDate = date 2022 Sep 14
  firstRegularPeriodDate = date 2022 Sep 20
  lastRegularPeriodDate = date 2023 Jun 20
  maturityDate = date 2023 Sep 14
  firstRegularPeriodDateFixLeg = date 2022 Sep 20
  lastRegularPeriodDateFixLeg = firstRegularPeriodDateFixLeg
  referenceRateId = "USD/LIBOR/3M"
  referenceRateOneMonthId = "USD/LIBOR/1M"
  fixRate = 0.02
  paymentPeriod = Regular M
  paymentPeriodMultiplier = 3
  dayCountConvention = Act360
  businessDayConvention = ModifiedFollowing
  issuerPartyRef = "Counterparty"
  clientPartyRef = "ExecutingParty"
```

The *issuerPartyRef* and the *clientPartyRef* variables are used to specify who pays each leg (see *payerPartyReference* below).

The fixed leg of the swap can now be defined using Daml data types that correspond to the *swapStream* schema:

```
swapStreamFixedLeg = SwapStream with
  payerPartyReference = clientPartyRef
  receiverPartyReference = issuerPartyRef
  calculationPeriodDates = CalculationPeriodDates with
    id = "fixedLegCalcPeriodDates"
```

(continues on next page)

(continued from previous page)

```

effectiveDate = AdjustableDate with
  unadjustedDate = issueDate
  dateAdjustments = BusinessDayAdjustments with
    businessDayConvention = NoAdjustment
    businessCenters = []
terminationDate = AdjustableDate with
  unadjustedDate = maturityDate
  dateAdjustments = BusinessDayAdjustments with
    businessDayConvention = ModifiedFollowing
    businessCenters = holidayCalendarIds
calculationPeriodDatesAdjustments = CalculationPeriodDatesAdjustments with
  businessDayConvention = ModifiedFollowing
  businessCenters = holidayCalendarIds
firstPeriodStartDate = None
firstRegularPeriodStartDate = Some firstRegularPeriodDateFixLeg
lastRegularPeriodEndDate = Some lastRegularPeriodDateFixLeg
calculationPeriodFrequency = CalculationPeriodFrequency with
  periodMultiplier = 1
  period = Regular Y
  rollConvention = DOM 20
paymentDates = PaymentDates with
  calculationPeriodDatesReference = "fixedLegCalcPeriodDates"
  paymentFrequency = PaymentFrequency with
    periodMultiplier = 1
    period = Regular Y
  firstPaymentDate = Some firstRegularPeriodDateFixLeg
  lastRegularPaymentDate = Some lastRegularPeriodDateFixLeg
  payRelativeTo = CalculationPeriodEndDate
  paymentDatesAdjustments = BusinessDayAdjustments with
    businessDayConvention = ModifiedFollowing
    businessCenters = holidayCalendarIds
  paymentDaysOffset = None
resetDates = None
calculationPeriodAmount = CalculationPeriodAmount with
  calculation = Calculation with
    notionalScheduleValue = NotionalSchedule_Regular NotionalSchedule with
      id = "fixedLegNotionalSchedule"
    notionalStepSchedule = NotionalStepSchedule with
      initialValue = 1000000.0
      step = []
      currency = "USD"
    rateTypeValue = RateType_Fixed FixedRateSchedule with
      initialValue = fixRate
      step = []
    dayCountFraction = dayCountConvention
    compoundingMethodEnum = None
stubCalculationPeriodAmount = None
principalExchanges = None

```

As you can see, the [Daml SwapStream data type](#) matches the [swapStream FpML schema](#). Please note that the actual parsing from FpML to Daml is not done by this template. It has to be implemented on the client side.

Similarly, the floating leg of the swap is defined like this:

```

swapStreamFloatingLeg = SwapStream with
payerPartyReference = issuerPartyRef
receiverPartyReference = clientPartyRef
calculationPeriodDates = CalculationPeriodDates with
  id = "floatingLegCalcPeriodDates"
  effectiveDate = AdjustableDate with
    unadjustedDate = issueDate
    dateAdjustments = BusinessDayAdjustments with
      businessDayConvention = NoAdjustment
      businessCenters = []
  terminationDate = AdjustableDate with
    unadjustedDate = maturityDate
    dateAdjustments = BusinessDayAdjustments with
      businessDayConvention = ModifiedFollowing
      businessCenters = holidayCalendarIds
  calculationPeriodDatesAdjustments = CalculationPeriodDatesAdjustments with
    businessDayConvention = ModifiedFollowing
    businessCenters = holidayCalendarIds
  firstPeriodStartDate = None
  firstRegularPeriodStartDate = Some firstRegularPeriodDate
  lastRegularPeriodEndDate = Some lastRegularPeriodDate
  calculationPeriodFrequency = CalculationPeriodFrequency with
    periodMultiplier = paymentPeriodMultiplier
    period = paymentPeriod
    rollConvention = DOM 20
paymentDates = PaymentDates with
  calculationPeriodDatesReference = "floatingLegCalcPeriodDates"
  paymentFrequency = PaymentFrequency with
    periodMultiplier = paymentPeriodMultiplier
    period = paymentPeriod
  firstPaymentDate = Some firstRegularPeriodDate
  lastRegularPaymentDate = Some lastRegularPeriodDate
  payRelativeTo = CalculationPeriodEndDate
  paymentDatesAdjustments = BusinessDayAdjustments with
    businessDayConvention = ModifiedFollowing
    businessCenters = holidayCalendarIds
  paymentDaysOffset = None
resetDates = Some ResetDates with
  calculationPeriodDatesReference = "floatingLegCalcPeriodDates"
  resetRelativeTo = CalculationPeriodStartDate
  fixingDates = FixingDates with
    periodMultiplier = -2
    period = D
    dayType = Some Business
    businessDayConvention = NoAdjustment
    businessCenters = fixingHolidayCalendarId
  resetFrequency = ResetFrequency with
    periodMultiplier = paymentPeriodMultiplier
    period = paymentPeriod
  resetDatesAdjustments = ResetDatesAdjustments with
    businessDayConvention = ModifiedFollowing
    businessCenters = holidayCalendarIds
calculationPeriodAmount = CalculationPeriodAmount with
  calculation = Calculation with
    notionalScheduleValue = NotionalSchedule_Regular NotionalSchedule with
      id = "floatingLegNotionalSchedule"

```

(continues on next page)

(continued from previous page)

```

    notionalStepSchedule = NotionalStepSchedule with
      initialValue = 1000000.0
      step = []
      currency = "USD"
  rateTypeValue = RateType_Floating FloatingRateCalculation with
    floatingRateIndex = referenceRateId
    indexTenor = Some Period with
      periodMultiplier = paymentPeriodMultiplier
      period = M
    spreadSchedule = [SpreadSchedule with initialValue = 0.005]
    finalRateRounding = None
  dayCountFraction = dayCountConvention
  compoundingMethodEnum = Some Straight
  stubCalculationPeriodAmount = Some StubCalculationPeriodAmount with
    calculationPeriodDatesReference = "floatingLegCalcPeriodDates"
    initialStub = Some $ StubValue_StubRate 0.015
    finalStub = Some $ StubValue_FloatingRate
    [ StubFloatingRate with
      floatingRateIndex=referenceRateOneMonthId
      indexTenor = Some (Period with period = M; periodMultiplier = 1)
    , StubFloatingRate with
      floatingRateIndex = referenceRateId
      indexTenor = Some (Period with period = M; periodMultiplier = 3)
    ]
  principalExchanges = None

```

There are three main ways to define which interest rate should be used for a stub period. They are all included in the fix or floating leg above, either in the initial or in the final stub period. In short, it depends on the content of [StubCalculationPeriodAmount](#):

1. *None*: No special stub rate is provided. Instead, use the same rate as was specified in the corresponding [Calculation](#).
2. *Specific stubRate*: Use this specific fix rate.
3. *Specific floatingRate*: Use this specific floating rate (if one rate is provided). If two rates are provided: use linear interpolation between the two rates.

Finally, we create the FpML swap instrument:

```

let
  instrument = InstrumentKey with
    issuer
    depository
    id = Id label
    version = "0"
    holdingStandard

  cid <- submitMulti [issuer] [publicParty] do
    exerciseCmd fpmlSwapFactoryCid FpmlSwapFactory.Create with
      fpml = Fpml with
        instrument
        description
        swapStreams
        issuerPartyRef
        currencies
        calendarDataProvider

```

(continues on next page)

(continued from previous page)

```
lastEventTimestamp
observers = fromList observers
```

Once this is done, you can create a holding on it. In this particular example trade, the notional is specified in the FpML instrument. This means that you would only book a unit holding (quantity=1.0) on the instrument.

19.12.3 Frequently Asked Questions

19.12.3.1 Why do the swaps have an issuer?

In the case of bonds, the instrument has a well-defined issuer. This is not necessarily the case for swaps, where two counterparties A and B swap the payments associated with each leg. However, in practice one of the counterparties is often a swap dealer, who shares some of the characteristics of a bond issuer. For the purpose of lifecycling in Daml Finance, we require one of the counterparties to take the role as issuer. This counterparty will serve as calculation agent and provide the observables required to calculate the swap payments.

The documentation of the Daml Finance asset model contains an [OTC swap example](#).

19.13 Generic Instrument

The [Generic Instrument](#) provides a flexible framework to model and lifecycle custom payoffs in Daml Finance. It encapsulates the [Contingent Claims](#) library, which gives us the tools to model the economic terms of the payoff.

To follow the code snippets used in this page in Daml Studio, you can [clone the Daml Finance repository](#) and run the scripts in the [Instrument/Generic/Test/Intermediated/BondCoupon.daml](#) and [Instrument/Generic/Test/EuropeanOption.daml](#) files.

The Generic Instrument and the Contingent Claims library are introduced in the [Payoff Modeling tutorial](#), which we encourage you to check out.

19.13.1 How to create a Generic Instrument

19.13.1.1 Define the Claim of a Bond

Consider a fixed rate bond which pays a 4% coupon *per annum* with a coupon period of 6 months. Assume that there are two coupons remaining until maturity: one to be paid today and one to be paid in 180 days. This can be modeled in the following way:

```
let
  today = toDateUTC now
  expiry = addDays today 180
  bondLabel = "ABC.DE 4% p.a. " <> show expiry <> " Corp"
  claims = mapClaimToUTCTime $ andList
    [ when (at today) $ scale (Const 0.02) $ one cashInstrument
    , when (at expiry) $ scale (Const 0.02) $ one cashInstrument
```

(continues on next page)

(continued from previous page)

```
, when (at expiry) $ scale (Const 1.0) $ one cashInstrument
]
```

Now that we have specified the economic terms of the payoff we can create a generic instrument:

```
instrument <-
  originateGeneric csd issuer bondLabel TransferableFungible "Bond" now□
↳ claims pp now
```

On every coupon payment date, the issuer will need to lifecycle the instrument. This will result in a lifecycle effect for the coupon, which can then be claimed and settled. This process is described in detail in [Getting Started: Lifecycling](#).

19.13.1.2 Define the Claim of a European Option

Alternatively, if you want to model a European Option instead, you can define the claim as follows

```
let
  exerciseClaim = scale (Observe spot - Const strike) $ one ccY
  option = european maturity exerciseClaim
```

This uses the [european](#) builder function, which is included in [Contingent Claims](#).

Compared to the bond, where the passage of time results in a coupon payment being due, the option instrument requires a manual *Election*: the holder of the instrument holding needs to choose whether or not to exercise the option. How this is done is described in the next section.

19.13.2 How to lifecycle a Generic Instrument

19.13.2.1 Election based lifecycling of Contingent Claims based instruments

We describe how to lifecycle an option instrument (which can be *Exercised* or *Expired*), but the same concepts apply to other Election based instruments (for example, a callable bond that can be *Called* or *NotCalled*). A similar workflow is also applicable to some of the instruments available in the Bond, Swap, and Option packages.

First, an Election factory is created:

```
-- Create election offers to allow holders to create elections
electionFactoryCid <- submit broker do
  toInterfaceContractId <$> createCmd Election.Factory with
    provider = broker
    observers = Map.fromList pp
```

Then, election offers are created for the different election choices that are available. Specifically, for option instruments, an election offer to exercise is created:

```
exerciseElectionFactoryCid <- submit broker do
  createCmd ElectionOffer with
    provider = broker
    id = Id "EXERCISE"
    description = "OPTION-AAPL - Exercise"
```

(continues on next page)

(continued from previous page)

```
claim = "EXERCISE"
observers = Set.singleton publicParty
instrument = genericInstrument
factoryCid = electionFactoryCid
```

Similarly, an election offer to expire the option is also created:

```
expireElectionFactoryCid <- submit broker do
  createCmd ElectionOffer with
    provider = broker
    id = Id "EXPIRE"
    description = "OPTION-AAPL - Expire"
    claim = "EXPIRE"
    observers = Set.singleton publicParty
    instrument = genericInstrument
    factoryCid = electionFactoryCid
```

Assuming the investor wants to exercise the option, an election candidate contract is created. In order to do this, the investor presents a holding for which an election should be made, and also specifies the amount that this election applies to. This amount cannot exceed the quantity of the holding:

```
-- One cannot exercise for more units than they own
submitMultiMustFail [investor1] [publicParty] do
  exerciseCmd exerciseElectionFactoryCid CreateElectionCandidate with
    elector = investor1
    electionTime = dateToDateClockTime maturity
    holdingCid = investor1GenericHoldingCid
    amount = 5000.0
```

Instead, the elected amount must be the same as the holding quantity, or lower:

```
-- Create election
exerciseOptionProposalCid <- submitMulti [investor1] [publicParty] do
  exerciseCmd exerciseElectionFactoryCid CreateElectionCandidate with
    elector = investor1
    electionTime = dateToDateClockTime maturity
    holdingCid = investor1GenericHoldingCid
    amount = 500.0
```

A time event is also required to indicate when the election is made:

```
currentTimeCid <- createDateClock (Set.singleton broker) maturity mempty
```

It is now possible to create the *Election*:

```
exerciseOptionCid <- submit broker do
  exerciseCmd exerciseOptionProposalCid ValidateElectionCandidate with
    currentTimeCid
```

Note: these templates (election offer and election candidate) are not considered a core part of the Daml Finance library. There can be different processes to create the Election, so this is rather application specific. Still, in order to showcase one way how this could be done, this workflow is included here for convenience.

The [Election](#) has a flag `electorIsOwner`, which indicates whether the election is on behalf of the owner of the holding. This is typically the case for options, where the option holder has the right, but not the obligation, to exercise the option. On the other hand, for callable bonds it is not the holding owner (the bond holder) who gets to decide whether the bond is redeemed early. Instead, it is the counterparty. In this case, `electorIsOwner` would be false.

A lifecycle rule is required to specify how to process the Election:

```
-- Apply election to generate new instrument version + effects
lifecycleRuleCid <- toInterfaceContractId <$> submit bank do
  createCmd Lifecycle.Rule with
    providers = Set.singleton bank
    observers = mempty
    lifecycler = broker
    id = Id "LifecycleRule"
    description = "Rule to lifecycle a generic instrument"
```

This is similar to time-based lifecycling.

Finally, it is possible to apply the Election according to the lifecycle rule provided:

```
(Some exercisedOption, [effectCid]) <- submit broker do
  exerciseCmd exerciseOptionCid Election.Apply with
    observableCids = [observableCid]
    exercisableCid = lifecycleRuleCid
```

This creates lifecycle effects, which can be claimed and settled in the usual way (as described in [Getting Started: Lifecycling](#)). However, the holding contract used to claim the effect must be compatible with the election that has been made: if Alice made an election and `electorIsOwner = True`, then only a holding where `owner = alice` will be accepted.

19.13.3 Frequently Asked Questions

19.13.3.1 When is a Generic Instrument preferred over a bond or swap?

The previously described instruments (e.g. [Bonds](#) and [Swaps](#)) have the advantage that the instrument terms are reflected as template variables. Also, the name of the template directly indicates what type of instrument it is.

The Generic instrument has the advantage that it provides a flexible framework for defining new payoffs in an ad-hoc manner. This can be useful for prototyping or in a structuring context. It also enables one-off trades for which no other instrument is available.

19.13.4 Contingent Claims

19.13.4.1 Introduction

Contingent Claims is a library for modeling financial instruments in Daml. An instrument is represented by a tree of [Claims](#), which describe future contractual events (cashflows and other effects) between two parties as well as the conditions under which these contractual events occur.

The library offers lifecycling capabilities, as well as an (experimental) valuation semantics to map a claim to a mathematical expression that can be used for no-arbitrage pricing.

Examples of how to create and lifecycle contracts using Contingent Claims can be found in the [Payoff Modeling tutorial](#).

In the following we present a user guide for getting started with Contingent Claims instrument modeling. It is meant to teach the basics of the framework, but does not cover every aspect. The work is based on the papers [Cit1] and [Cit2], and we recommend that you refer to these for an in-depth understanding of how it works.

19.13.4.2 The Model

The approach taken in the papers is to model financial instruments by their cashflows. This should be familiar to anyone having taken a course in corporate finance or valuation. Let's start with an example:

The picture above represents the cashflows of a fixed-rate bond. Or alternatively, you can think of it as a mortgage, from the point of view of the bank: there are interest payments at regular intervals (the small arrows), and a single repayment of the loan at maturity (the big arrow on the right). So how do we go about modelling this?

We use the following data type, slightly simplified from [Claim](#):

```
data Claim a
  = zero
  | one a
  | give (Claim a)
  | and with lhs: Claim a, rhs: Claim a
  | or with lhs: Claim a, rhs: Claim a
  | scale with k: Date -> Decimal, claim: Claim a
  | when with predicate: Date -> Bool, claim: Claim a
  | anytime with predicate : Date -> Bool, claim: Claim a
  | until with predicate : Date -> Bool, claim: Claim a
```

There are a couple of things to consider.

First note that the constructors of this data type create a tree structure. The leaf constructors are `zero` and `one a`, and the other constructors create branches (observe they call `Claim a` recur-

sively). The constructors are just functions, and can be combined to produce complex *effects*. For example, to represent the above bond, we could write the following:

```
when (time == t_0) (scale (pure coupon) (one "USD")) `and` ...
```

Let's look at the constructors used in the above expression in more detail:

`one "USD"` means that the acquirer of the contract receives one unit of the asset, parametrised by `a`, *immediately*. In this case we use a 3-letter ISO code to represent a currency, but you can use your own type to represent any asset.

`scale (pure coupon)` modifies the *magnitude* of the arrow in the diagram. For example, in the diagram, the big arrow would have a distinct scale factor from the small arrows. In our example, the scale factor is constant: `pure coupon = const coupon`, however, it's possible to have a scale factor that depends on an unobserved value, such as a stock price, the weather, or any other measurable quantity.

`when (time == t_0)` tells us where along the x-axis the arrow is placed, i.e., it modifies the point in time when the claim is acquired. The convention is that this must be the first instant that the predicate (`time == t_0` in this case) is true. In our example it is a point, but again, we could have used an expression with an unknown quantity, for example `spotPrice > pure k`, and it would trigger *the first instant* that the expression becomes true.

`and` is used to chain multiple expressions together. Remember that in the data definition above, each constructor is a function: `and : Claim a -> Claim a -> Claim a`. We use the Daml backtick syntax to write `and` as an infix operator, for legibility.

Additionally, there are several constructors which were not used in the above example:

`zero`, used to indicate an absence of obligations. While it may not make sense to create a `zero` claim, it could, for example, result from applying a function on a tree of claims.

`give` would flip the direction of the arrows in our diagram. For example, in a swap we could use `give` to distinguish the received/paid legs.

`or` is used to give the bearer the right to choose between two different claims. This is typically used for options.

`anytime` is like `when`, except it allows the bearer to choose (vs. no choice) acquisition within a region (or timeframe), vs. a specific point in time.

`until` is used to adjust the expiration (*horizon* in [\[Cit1\]](#)) of a claim. Typically, it is used with `anytime` to limit aforesaid acquisition region.

The tree produced by our expression (corresponding to the cashflow figure above) looks like this:

19.13.4.3 Composition and Extensibility

Although we could model every subsequent arrow the way we did the first one, as good programmers we wish to avoid repeating ourselves. Hence, we could write functions to re-use subexpressions of the tree. But which parts should we factor out? It turns out that Finance 101 comes to the rescue again. Fixed income practitioners will typically model a fixed-rate bond as a sum of zero-coupon bonds. That's how we model them in [Claims.Util.Builders](#). Below are slightly simplified versions:

```
zcb maturity principal asset =
  when (time == maturity) (scale (O.pure principal) (one asset))
```

Here we've just wrapped our expression from the previous section in a function `zcb`, that we can reuse to build a fixed-rate bond:

```
fixed : Decimal -> Decimal -> a -> [Date] -> Claim a
fixed principal coupon asset [] = zero
fixed principal coupon asset [maturity] =
  zcb maturity coupon asset `and` zcb maturity principal asset
fixed principal coupon asset (t :: ts) =
  zcb t coupon asset `and` fixed principal coupon asset ts
```

We define the fixed rate bond by induction, iterating over a list of dates `[t]`, and producing multiple zero-coupon bonds `zcb` combined together with `and`:

The first definition covers the trivial case where we pass an empty list of dates.

The second definition handles the base case, at maturity: we create both a coupon (interest) payment, and the principal payment.

The third definition is the induction step; it peels the first element off the list, and calls itself recursively on the tail of the list, until it reaches the base case at maturity.

This re-use of code is prevalent throughout the library. It's great as it mirrors how instruments are defined in the industry. Let's look at yet another example, a fixed vs floating USD/EUR swap.

```
type Ccy = Text
usdVsEur : [Date] -> Claim Ccy
usdVsEur =
  fixed 100.0 0.1 "USD" `swap` floating (spot "EURUSD" * pure 100.0) (spot
    ↪ "EURUSD") "EUR"
```

We define it in terms of its two legs, *fixed* and *floating*, which themselves are functions. We use *swap* in infix form, and partially apply it - it takes a final `[Date]` argument which we omit, hence the resulting signature `[Date] -> Claim Ccy`.

As you can see, not only is this approach highly composable, but it also mirrors the way derivative instruments are modelled in finance.

Another major advantage of this approach is its extensibility. Unlike a traditional approach, where we might in an object-oriented language represent different instruments as classes, in the cashflow approach, we do not need to enumerate possible asset classes/instruments *a priori*. This is especially relevant in a distributed setting, where parties must execute the same code, i.e., have the same `*.dars` on their ledger to interact. In other words, party A can issue a new instrument, or even write a new combinator function that is in a private `*.dar`, while being able to trade with party B, who has no knowledge of this new `*.dar`.

19.13.4.4 Concerning Type Parameters

The curious reader may have noticed that the signature we gave for `data Claim` is not quite what is in the library, where we have `data Claim t x a o = Claim Date Decimal a a`. In our examples, we have specialised this to `type Claim' t x a o = Claim Date Decimal a a`. Parameterising these variables allows us to reason about *Assets* and *Observations* that appear in *Claims* as function-like objects. The main use of this is to create claims with 'placeholders' for actual parameters, that can later be 'filled in' by mapping over them (`mapParams`).

The Time Parameter

`t` is used to represent the first input argument to an *Observation*, and above we used `Date` for this purpose. One reason this has been left parametrised is to be able to distinguish different calendar and day count conventions at the type level. This is quite a technical topic, but it suffices to know that for financial calculations, interest is not always accrued the same way, nor is settlement possible every day, as this depends on local jurisdictions or market conventions. Having different types makes this explicit at the instrument level.

Another use for this is expressing time as an ordinal values, representing e.g. days from issue. Such a *Claim* can be used repeatedly to represent instruments issued at different dates, but with the same durations. For example, consider a series of listed futures or options which are issued with quarterly/monthly maturities - their duration is about the same, but they are issued on different dates.

The Asset Parameter

`a`, as we already explained, is the type used to represent assets in your application. Keeping this generic means the library can be used with any asset representation. For example, you could use one of the instrument implementations in Daml Finance, but are not forced to do so.

The Observation Parameter

`o` is the type used to represent `Observations`, which are time-dependent quantities that can be observed at any given time (such as the `EURUSD` exchange rate in the example above).

The Value Parameter

`x` is the ‘output’ type of an `Observation`, but it can also serve as input when defining a constant observation using, e.g., `Observation.pure 10.08`.

19.13.4.5 Lifecycling

So far we’ve learned how to model arbitrary financial instruments by representing them as trees of cashflows. We’ve seen that these trees can be constructed using the type constructors of `data Claim`, and that they can be factored into more complex building blocks using function composition. But now that we have these trees, what can we do with them?

The original paper [Cit1] focuses on using these trees for valuing the instruments they represent, i.e., finding the ‘fair price’ that one should pay for these cashflows. Instead, we’ll focus here on a different use case: the lifecycling (aka safekeeping, processing corporate actions) of these instruments.

Let’s go back to our fixed-rate bond example, above. We want to process the coupon payments. There is a function in the [Lifecycle module](#) for doing exactly this:

```
type C t a o = Claim t Decimal a o

-- | Used to specify pending payments.
data Pending t a = Pending
  with
    t : t
    -- ^ Payment time.
    amount : Decimal
    -- ^ Amount of asset to be paid.
    asset : a
    -- ^ Asset in which the payment is denominated.
  deriving (Eq, Show)

-- | Returned from a `lifecycle` operation.
data Result t a o = Result
  with
    pending : [Pending t a]
    -- ^ Payments requiring settlement.
    remaining : C t a o
    -- ^ The tree after lifecycled branches have been pruned.
```

(continues on next page)

(continued from previous page)

```

deriving (Eq, Show)

-- | Collect claims falling due into a list, and return the tree with those nodes
--   pruned.
-- `m` will typically be `Update`. It is parametrised so it can be run in a
--   `Script`. The first
--   argument is used to lookup the value of any `Observables`. Returns the pruned
--   tree + pending
--   settlements up to the provided market time.
lifecycle : (Ord t, Eq a, CanAbort m)
  => (o -> t -> m Decimal)
  -- ^ Function to evaluate observables.
  -> C t a o
  -- ^ The input claim.
  -> t
  -- ^ The input claim's acquisition time.
  -> t
  -- ^ The current market time. This is the time up to which observations are
  --   known.
  -> m (Result t a o)

```

This may look daunting, but let's look at an example in [ContingentClaims/Test/FinancialContract.daml](#) to see this in action:

```

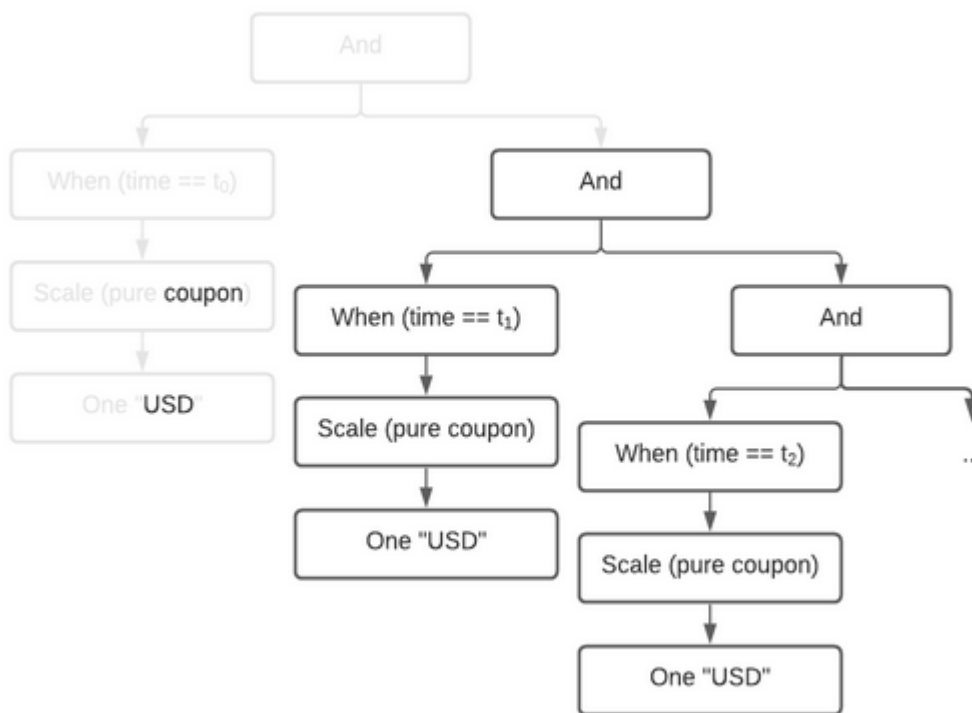

do
  t <- toDateUTC <$> getTime
  let
    getSpotRate isin t = do
      (_, Quote{close}) <- fetchByKey (isin, t, bearer)
      pure close
  lifecycleResult <- Lifecycle.lifecycle getSpotRate claims
  acquisitionTime t

```

The first argument to `lifecycle`, `getSpotRate`, is a function taking an ISIN (security) code, and today's date. All this does is fetch a contract from the ledger that is keyed by these two values, and extract the price of the security.

The last two arguments are simply the claims we wish to process, and today's date, evaluated using `getTime`.

The return value, `lifecycleResult`, will contain both the remaining tree after lifecycling, and any assets that need to be settled. In our running bond example, we would extract the `coupon` from the first payment, and return it, along with the rest of the tree, after that branch has been pruned (depicted greyed-out below):

You may wonder why we've separated the settlement procedure from the lifecycle function. The reason is that we can't assume that settlement will happen on-chain; if it does, that is great, as we can embed this call into a template choice, and lifecycle and settle atomically. However, in the case where settlement must happen off-chain, there's no way to to do this in one step. This design supports both choices.

19.13.4.6 Pricing (Experimental)

This is an *experimental* feature. Expect breaking changes.

The `ContingentClaims.Valuation.Stochastic` module can be used for valuation. There is a `fapf` function which is used to derive a *fundamental asset pricing formula* for an arbitrary `Claim` tree. The resulting AST is represented by `Expr`, but can be rendered as XML/MathML with the provided `MathML.presentation` function, for display in a web browser. See the `Test/Pricing` module for examples. Here is a sample rendering of a margrabe option:

$$\begin{aligned} & \left(\frac{\text{USD}}{T} \right) \times \left(\frac{\text{AMZN}}{T} - \frac{\text{APPL}}{T} \right) \\ & \leq 0.0 \\ & \left(\frac{\text{AMZN}}{T} - \frac{\text{APPL}}{T} \right) \times 0.0 \\ & \leq \left(\frac{\text{AMZN}}{T} - \frac{\text{APPL}}{T} \right) \times 1.0 \\ & \left(\frac{\text{AMZN}}{T} - \frac{\text{APPL}}{T} \right) \times 1.0 \end{aligned}$$

You can cut-and-paste this into a web page in 'developer mode' in any modern browser.

19.13.4.7 References

The papers can be downloaded from [Microsoft Research](#).

Chapter 20

Packages

This section explains the different packages in Daml Finance. It describes the modules contained in each package and points to resources for learning how to use the packages (either a tutorial or a test that describes how to use the package step-by-step).

20.1 Interface Packages

This section lists the interface packages contained within Daml Finance:

20.1.1 `Daml.Finance.Interface.Holding.V4`

This package contains the *interface* and utility functions for holdings. It has the following modules:

Factory: Interface for a holding factory used to create (credit) and archive (debit) holdings

Holding: Interface for a base holding which includes locking capabilities

Fungible: Interface for a fungible holding which allows splitting and merging

Transferable: Interface for a transferable holding, i.e., where ownership can be transferred to other parties

Util: Utility functions related to holdings, e.g., getting the amount or the instrument of a holding

The [Asset Model](#) page explains the relationship between instruments, holdings, and accounts. Check out the [Transfer tutorial](#) for a description on how to create a holding on an instrument and how to transfer it between accounts.

The following diagram shows the incoming and outgoing dependencies for this package:

20.1.1.1 Changelog

20.1.1.2 Changelog

Daml.Finance.Interface.Holding.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Holding

Version 3.0.0

Update of SDK version and dependencies.

Factored out the locking logic from the base *Holding* interface to a separate interface called *Lockable* of the *Daml.Finance.Interface.Util.V3* package.

Updated the *Daml.Finance.Interface.Holding.V4.Factory* to use a key, employing a *Reference* template and the *HoldingFactoryKey* data type. Additionally, It also requires the *Disclosure.I* and has a *getKey* method and *Remove* choice.

Removed the requirement that a *Fungible.I* requires *Transferable.I*.

Renamed *Base* to *Holding*.
Renamed the *F* type synonym to *I*.

Version 2.0.0

Update of SDK version and dependencies.
Remove implementation of *Remove* choice from factory templates.
Removed unnecessary *ArchiveFungible* choice.
Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure*, *asBase*, and *asTransferable* methods were removed).
Fix to signature of *disclose* (removed the *actor* argument).

20.1.2 Daml.Finance.Interface.Account.V4

This package contains the *interface* and utility functions for accounts. It has the following modules:

Factory: Interface that allows implementing templates to create and remove accounts
Account: Interface which represents an established relationship between a custodian and an owner. It specifies parties controlling incoming and outgoing transfers, and allows for crediting and debiting holdings
Util: Utility functions related to accounts, e.g., getting the custodian or the owner of an account

20.1.2.1 Changelog

20.1.2.2 Changelog

Daml.Finance.Interface.Account.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Account

Version 3.0.0

Update of SDK version and dependencies.
Removed the *ContractId Holding.Factory* from the account view.
The *Remove* choice, which was previously a choice of the *Factory*, has now been reassigned to the *Account*.
The *Create* choice of the account's *Factory* has been adapted; it now takes a *HoldingFactoryKey* instead of the *ContractId Daml.Finance.Interface.Holding.V4.Factory* as input
Renamed the *F* type synonym to *I*.

Version 2.0.0

Update of SDK version and dependencies.

Remove type synonym for `AccountKey`.

Make use of the `requires` keyword to enforce the interface hierarchy (in particular the `asDisclosure` method was removed).

20.1.3 Daml.Finance.Interface.Settlement.V4

This package contains the *interface* for settlement. It has the following modules:

[RouteProvider](#): Interface for providing a discovery mechanism for settlement routes

[Instruction](#): Interface for providing a single instruction to transfer an asset at a custodian

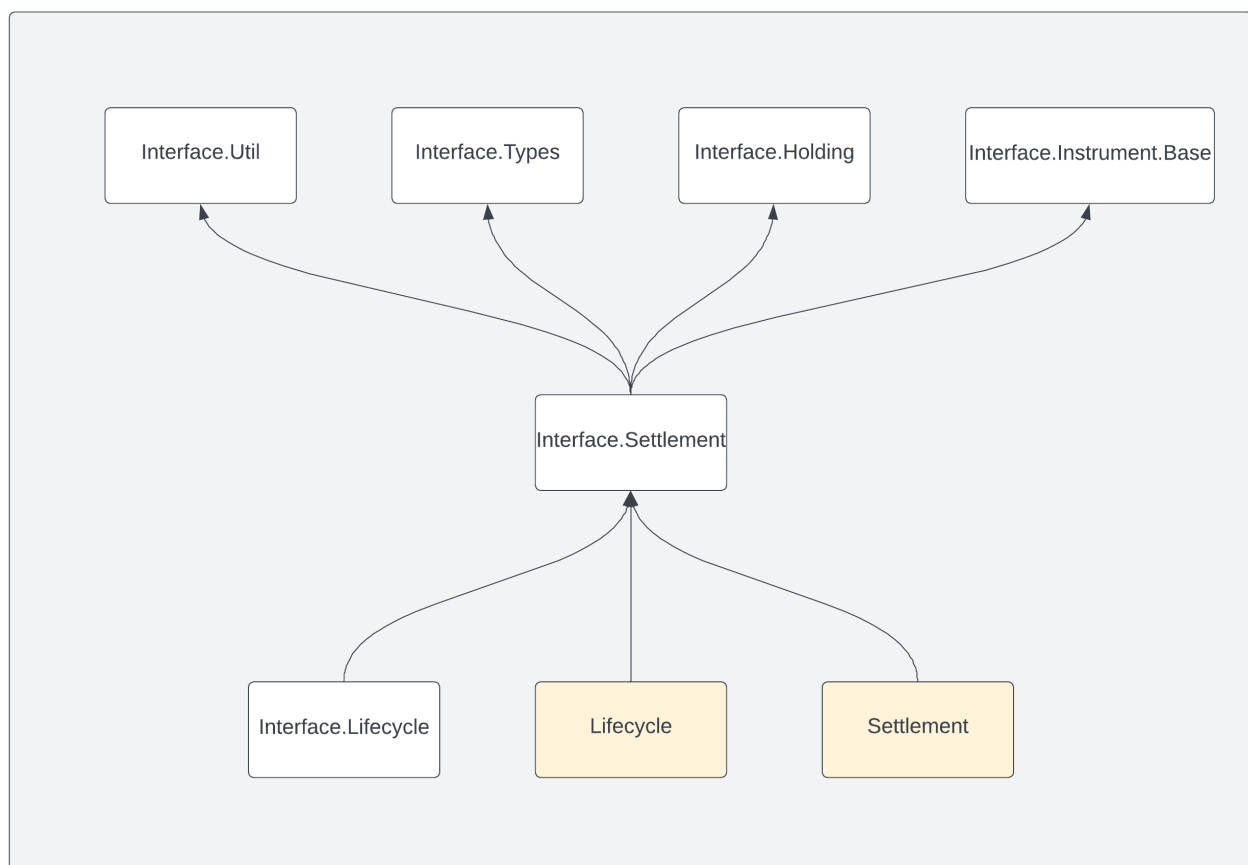

[Batch](#): Interface for atomically executing instructions, i.e., settling *Transferables*

[Factory](#): Interface used to generate a batch and associated instructions

[Types](#): Types required in the settlement process, e.g., *Step*, *RoutedStep*, *Allocation*, and *Approval*

The [Settlement](#) page contains an overview of the settlement process and explains the relationship between instructions and batches. Check out the [Settlement tutorial](#) for a description on how to use the settlement workflow in practice.

The following diagram shows the incoming and outgoing dependencies for this package:

20.1.3.1 Changelog

20.1.3.2 Changelog

Daml.Finance.Interface.Settlement.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Settlement

Version 3.0.0

Update of SDK version and dependencies.

For the *Batch* and *Instruction*, the *requestors : Parties* field was split up into an *instructor : Party* as maintainer of the *Instruction* key, and *consenters : Parties* as additional signatories. The *Batch* and *Instruction* views were amended accordingly.

Version 2.0.0

Update of SDK version and dependencies.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* was removed).

20.1.4 Daml.Finance.Interface.Lifecycle.V4

This package contains the *interface* for lifecycle related processes. It contains the following modules:

Effect: Interface for contracts exposing effects of lifecycling processes, e.g., the payment resulting from a bond coupon

Election: Interface to allow for elections to be made on claim based instruments

Election.Factory: Factory interface to instantiate elections on claim based instruments

Event: Interface for a lifecycle event. An event is any contract that triggers the processing of a lifecycle rule. Events can be, e.g., dividend announcements or simply the passing of time.

Event.Distribution: Event interface for the distribution of units of an instrument for each unit of a target instrument (e.g. share or cash dividends)

Event.Replacement: Event interface for the replacement of units of an instrument with a basket of other instruments (e.g. stock merger)

Event.Time: Event interface for events that signal the passing of (business) time

Rule.Lifecycle: Interface implemented by rules that lifecycle and evolve instruments

Rule.Claim: Interface for contracts that allow holders to claim an *Effect* and generate settlement instructions

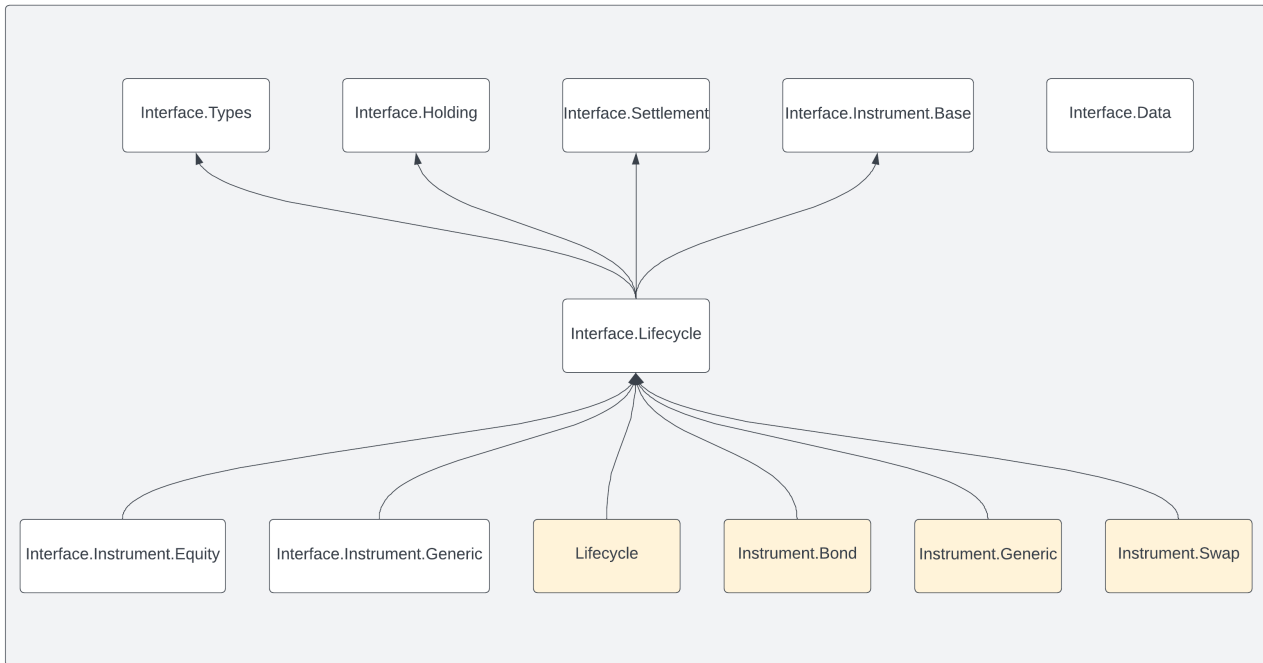

Observable.NumericObservable: Interface to observe time-dependent numerical values (e.g. a stock price or an interest rate fixing)

Observable.TimeObservable: Interface implemented by templates exposing time information

The *Lifecycling* page contains an overview of the lifecycle process and explains the relationship between events, lifecycle rules and effects. Check out the *Lifecycling tutorial* for a description on how

lifecycling works in practice. There is also the tutorial [How to implement a Contingent Claims-based instrument](#), which describes how claims are defined, how to use a `NumericObservable`, and how the `Lifecycle` interface is implemented for bonds.

The following diagram shows the incoming and outgoing dependencies for this package:

20.1.4.1 Changelog

20.1.4.2 Changelog

Daml.Finance.Interface.Lifecycle.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Lifecycle

Version 3.0.0

Update of SDK version and dependencies.

Renamed the *F* type synonym to *I*.

Changed the *Calculate* choice of the *Effect.I* to take a quantity as argument instead of a *ContractId Holding* (in order to not leak information about the holding to the effect provider).

Version 2.0.0

Update of SDK version and dependencies.
Remove implementation of *Remove* choice from factory interfaces.
Move the *Election* module from the *Generic* to the *Lifecycle* package.
Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asEvent* methods were removed).

20.1.5 Daml.Finance.Interface.Instrument.Base.V4

This package contains the *root interface* for all instruments. It contains the following modules:

Instrument: Root instrument abstraction containing basic properties that every instrument exhibits

20.1.5.1 Changelog

20.1.5.2 Changelog

Daml.Finance.Interface.Instrument.Base.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Base

Version 3.0.0

Update of SDK version and dependencies.
The *InstrumentKey* is extended by the *HoldingStandard* field.
Moved the *Remove* choice from the *Factory* to the *Instrument*.
Added *I* as type synonym for *Factory* (the *F* type synonym is to be deprecated).
Made the *issuer* a single-maintainer of the *Instrument* key.
Added an enumeration data type *HoldingStandard* to the *InstrumentKey* for referring to various holding standards.
Renamed the *F* type synonym to *I*.

Version 2.0.0

Update of SDK version and dependencies.
Removed type synonym for *InstrumentKey*.
Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* method was removed).

20.1.6 Daml.Finance.Interface.Claims.V4

This package contains the *interface* for Contingent Claims based instruments. It contains the following modules:

Claim: Interface implemented by templates that can be represented as a set of contingent claims

Dynamic.Instrument: Interface implemented by instruments that create Contingent Claims trees on-the-fly (i.e. the tree is not stored on disk as part of a contract, but created and processed in-memory)

Types: Types related to claims and what is required to represent claims (e.g. Deliverable and Observable)

20.1.6.1 Changelog

20.1.6.2 Changelog

Daml.Finance.Interface.Claims.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Claims

Version 3.0.0

Update of SDK version and dependencies.

Add general support to replay previous events of different types (not only elections).

Version 2.0.0

Update of SDK version and dependencies.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asBaseInstrument* method was removed).

20.1.7 Daml.Finance.Interface.Data.V4

This package contains the *interface* for inspecting and working with observables, which are used in the context of lifecycling. It contains the following modules:

Numeric.Observation.Factory: Interface for a factory used to create, remove and view a `Numeric.Observation`

Numeric.Observation: Interface for a time-dependent `Numeric.Observation`, where the values are explicitly stored on-ledger

Reference.HolidayCalendar.Factory: Interface for a factory used to create, remove and view a `HolidayCalendar`

Reference.HolidayCalendar: Interface for contracts storing holiday calendar data on the ledger

[Reference.Time](#): Interface for contracts that control business time, providing choices to advance or rewind time

20.1.7.1 Changelog

20.1.7.2 Changelog

Daml.Finance.Interface.Data.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Data

Version 3.1.0

Update of SDK version and dependencies.

Added *I* as type synonym for each *Factory* in the package (the *F* type synonyms are to be deprecated).

Version 3.0.0

Update of SDK version and dependencies.

Remove implementation of *Remove* choice from factory templates.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure*, *asNumericObservable*, and *asTimeObservable* methods were removed).

Version 2.0.0

Changed the signature of *advance* and *rewind* in the *Reference.Time* interface.

Dependencies update.

20.1.8 Daml.Finance.Interface.Types.Common.V3

This package contains common type definitions. They are defined in the following modules:

[Types](#): Various types related to keys, observers, parties, identifiers and quantities, which are commonly used in several packages

20.1.8.1 Changelog

20.1.8.2 Changelog

Daml.Finance.Interface.Types.Common.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Types.Common

Version 2.0.0

Update of SDK version and dependencies.

Added a *HoldingFactoryKey* data type used to key holding factories.

Added a *HoldingStandard* enumeration data type for referring to various holding standards, it is newly part of the *InstrumentKey*.

Version 1.0.1

Update of SDK version and dependencies.

20.1.9 Daml.Finance.Interface.Types.Date.V3

Financial instruments, especially those related to interest rates, often depend on periodic schedules. For example, consider a fixed rate bond with a coupon that should be paid every three months. Such a regular schedule sometimes results in a payment date falling on a weekend or on a holiday. Those dates need to be adjusted to business dates, according to the terms of the instrument.

This package contains types related to dates, in particular how to define regular schedules and how dates should be adjusted when they fall on non-business days. They are defined in the following modules:

Calendar: Types for holiday calendar data and how to adjust non-business days

Classes: Type class that specifies what can be converted to UTC time

DateOffset: Types for date offsets that can be used e.g. to specify a rate fixing date relative to the reset date in terms of a business days offset and an associated set of financial business centers.

DayCount: Type to specify the conventions used to calculate day count fractions. These are used to define the interest accrued during each schedule period, for example for a bond or a swap.

RollConvention: Types to define date periods and how to roll dates

Schedule: Types to define date schedules

Check out the [Fixed rate bond documentation](#) for a description of how to use these date related types in practice.

20.1.9.1 Changelog

20.1.9.2 Changelog

Daml.Finance.Interface.Types.Date.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Types.Date

Version 2.1.0

Update of SDK version and dependencies.

Added new day-count conventions: Act365NL, Basis30365, and Basis30E2360.

Version 2.0.1

Update of SDK version and dependencies.

Version 2.0.0

Introduce *ScheduleFrequency* data type.

Added *NoRollConvention* to *RollConventionEnum*. It applies to *D* and *W* periods.

PeriodicSchedule.frequency is of type *ScheduleFrequency* instead of *Frequency*.

20.1.10 Daml.Finance.Interface.Util.V3

This package contains the *interface* for the disclosure of contracts and some commonly used utility functions. They are defined in these modules:

Disclosure: An interface for managing the visibility of contracts for non-authorizing parties

Lockable: An interface for locking contracts, e.g., a holding or account

InterfaceKeys: An interface with utility functions for keying interfaces

Common: Different utility functions related to interfaces and assertions

20.1.10.1 Changelog

20.1.10.2 Changelog

Daml.Finance.Interface.Util.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Util

Version 2.1.0

Update of SDK version and dependencies.

Added a *Lockable* module containing the interface for locking (the *Acquire* and *Release* choices used to be part of the base *Holding* interface).

Created a module *InterfaceKey* with utility functions for keyed interfaces.

Version 2.0.0

Update of SDK version and dependencies.

Remove *mapWithIndex* utility function.

Remove the *HasImplementation* type class definition.

20.1.11 ContingentClaims.Core.V3

This package contains the *interface* to represent *Contingent Claims* trees. It contains data types and utility functions to process such trees. It also contains builder functions to facilitate the creation of trees using composition. The following modules are included:

Builders: Builder functions to compose trees from smaller building blocks

Internal.Claim: Internal data types to represent tree nodes

Claim: Smart constructors for the types defined in *Internal.Claim*

Observation: Data types to represent observations in trees

Util.Recursion: Utility functions to facilitate recursive traversal of trees

20.1.11.1 Changelog

20.1.11.2 Changelog

ContingentClaims.Core.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Bumps *daml-ctl* to 2.5.0.

ContingentClaims.Core

Version 2.0.1

Update of SDK version and dependencies.

Version 2.0.0

Update of SDK version and dependencies.

Add *orList* and *andList* smart constructors.

Add *ObserveAt* observation builder, used to explicitly state when an *Observation* should be observed.

Refactor *or* and *anytime* smart constructors to identify electable sub-trees by a textual tag.

20.1.12 Daml.Finance.Interface.Instrument.Bond.V3

This package contains the *interface* definitions for bond instruments. It contains the following modules:

Callable.Instrument: Instrument interface for callable bonds

Callable.Factory: Factory interface to instantiate callable bond instruments

Callable.Types: Type definitions to support callable bond instruments

FixedRate.Instrument: Instrument interface for fixed-rate bonds

FixedRate.Factory: Factory interface to instantiate fixed-rate bond instruments

FixedRate.Types: Type definitions to support fixed-rate bond instruments

FloatingRate.Instrument: Instrument interface for floating-rate bonds

FloatingRate.Factory: Factory interface to instantiate floating-rate bond instruments

FloatingRate.Types: Type definitions to support floating-rate bond instruments

InflationLinked.Instrument: Instrument interface for inflation-linked bonds

InflationLinked.Factory: Factory interface to instantiate inflation-linked bond instruments

InflationLinked.Types: Type definitions to support inflation-linked bond instruments

ZeroCoupon.Instrument: Instrument interface for zero-coupon bonds

ZeroCoupon.Factory: Factory interface to instantiate zero-coupon bond instruments

ZeroCoupon.Types: Type definitions to support zero-coupon bond instruments

20.1.12.1 Changelog

20.1.12.2 Changelog

Daml.Finance.Interface.Instrument.Bond.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Bond

Version 2.0.0

Update of SDK version and dependencies.

The *InstrumentKey* is extended by the *HoldingStandard* field.

The *Remove* choice was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Added *I* as type synonym for *Factory* (the *F* type synonym is to be deprecated).

Added support for SOFR style rates (via a compounded index) to the floating rate bond.
Added an enumeration data type *HoldingStandard* to the *InstrumentKey* for referring to various holding standards.
Renamed the *F* type synonym to *I*.

Version 1.0.0

Update of SDK version and dependencies.
The *Create* choice on the instrument factories returns the corresponding interface (rather than the base instrument interface).
Add *GetView* choice to all instrument interfaces.
Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asBaseInstrument* methods were removed).
Introduce a new callable bond instrument.
Add a *notional* field to all instruments.

Version 0.2.1

Dependencies update.

20.1.13 Daml.Finance.Interface.Instrument.Equity.V0

This package contains the *interface* definitions for equity instruments. It contains the following modules:

Instrument: Instrument interface for equities. It supports lifecycling events through the *DeclareDistribution*, *DeclareReplacement* and *DeclareStockSplit* choices.

Factory: Factory interface to instantiate equities

20.1.13.1 Changelog

20.1.13.2 Changelog

Daml.Finance.Interface.Instrument.Equity.V0

Version 1.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Equity

Version 0.4.0

Update of SDK version and dependencies.

The *InstrumentKey* is extended by the *HoldingStandard* field.

The *Remove* choice was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *I*.

Version 0.3.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factory returns the corresponding interface (rather than the base instrument interface).

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asBaseInstrument* methods were removed).

Rename *DeclareDividend* to *DeclareDistribution*.

20.1.14 Daml.Finance.Interface.Instrument.Generic.V4

This package contains the *interface* definitions for generic, contingent-claims-based instruments. It contains the following modules:

Instrument: Instrument interface for generic instruments

Factory: Factory interface to instantiate generic instruments

20.1.14.1 Changelog

20.1.14.2 Changelog

Daml.Finance.Interface.Instrument.Generic.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Generic.V4

Version 3.0.0

Update of SDK version and dependencies.

The *InstrumentKey* is extended by the *HoldingStandard* field.

The *Remove* choice was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *I*.

Version 2.0.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factory returns the corresponding interface (rather than the base instrument interface).

Move the *Election* module to the *Lifecycle* package. Also, refactor the *Election* to identify the elected sub-tree by a textual tag rather than the actual sub-tree.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure*, *asBaseInstrument*, and *asClaim* methods were removed).

20.1.15 Daml.Finance.Interface.Instrument.Option.V0

This package contains the *interface* definitions for various option instruments. It contains the following modules:

BarrierEuropeanCash.Instrument: Instrument interface for barrier options

BarrierEuropeanCash.Factory: Factory interface to instantiate barrier options

BarrierEuropeanCash.Types: Type definitions to support barrier options

Dividend.Instrument: Instrument interface for dividend options

Dividend.Factory: Factory interface to instantiate dividend options

Dividend.Types: Type definitions to support dividend options

Dividend.Election.Factory: Factory interface to instantiate elections for dividend options

EuropeanCash.Instrument: Instrument interface for cash-settled European options

EuropeanCash.Factory: Factory interface to instantiate cash-settled European options

EuropeanCash.Types: Type definitions to support cash-settled European options

EuropeanPhysical.Instrument: Instrument interface for physically settled European options

EuropeanPhysical.Factory: Factory interface to instantiate physically settled European options

EuropeanPhysical.Types: Type definitions to support physically settled European options

Types: Type definitions common to several instruments in this package

20.1.15.1 Changelog

20.1.15.2 Changelog

Daml.Finance.Interface.Instrument.Option.V0

Version 1.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Option.V0

Version 0.3.0

Update of SDK version and dependencies.

The *InstrumentKey* is extended by the *HoldingStandard* field.

Removed the *Remove* choice from the option dividend election *Factory*.

The *Remove* choice was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *I*.

Version 0.2.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factories returns the corresponding interface (rather than the base instrument interface).

Add instruments physically-settled European options, dividend options, barrier options.

Renamed cash-settled European options to *EuropeanCash*.

Added *GetView* choice to all instrument interfaces.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure*, *asBaseInstrument*, and *asEvent* methods were removed).

20.1.16 Daml.Finance.Interface.Instrument.StructuredProduct.V0

This package contains the *interface* definitions for various structured product instruments. It contains the following modules:

AutoCallable.Instrument: Instrument interface for Auto Callables

AutoCallable.Factory: Factory interface to instantiate Auto Callables

AutoCallable.Types: Type definitions to support Auto Callable

BarrierReverseConvertible.Instrument: Instrument interface for Barrier Reverse Convertibles

BarrierReverseConvertible.Factory: Factory interface to instantiate Barrier Reverse Convertibles

BarrierReverseConvertible.Types: Type definitions to support Barrier Reverse Convertibles

Types: Type definitions common to instruments in this package

20.1.16.1 Changelog

20.1.16.2 Changelog

Daml.Finance.Interface.Instrument.StructuredProduct.V0

Version 1.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

New *AutoCallable* instrument.

Daml.Finance.Interface.Instrument.StructuredProduct

Version 0.1.0

First release.

20.1.17 Daml.Finance.Interface.Instrument.Swap.V0

This package contains the *interface* definitions for various swap instruments. It contains the following modules:

- Asset.Instrument*: Instrument interface for asset swaps
- Asset.Factory*: Factory interface to instantiate asset swaps
- Asset.Types*: Type definitions to support asset swaps
- CreditDefault.Instrument*: Instrument interface for credit default swaps
- CreditDefault.Factory*: Factory interface to instantiate credit default swaps
- CreditDefault.Types*: Type definitions to support credit default swaps
- Currency.Instrument*: Instrument interface for currency swaps
- Currency.Factory*: Factory interface to instantiate currency swaps
- Currency.Types*: Type definitions to support currency swaps
- ForeignExchange.Instrument*: Instrument interface for foreign exchange swaps
- ForeignExchange.Factory*: Factory interface to instantiate foreign exchange swaps
- ForeignExchange.Types*: Type definitions to support foreign exchange swaps
- Fpml.Instrument*: Instrument interface for FpML swaps
- Fpml.Factory*: Factory interface to instantiate FpML swaps
- Fpml.FpmlTypes*: Specific FpML types used to support FpML swaps
- Fpml.Types*: Type definitions to support FpML swaps
- InterestRate.Instrument*: Instrument interface for interest rate swaps
- InterestRate.Factory*: Factory interface to instantiate interest rate swaps
- InterestRate.Types*: Type definitions to support interest rate swaps

20.1.17.1 Changelog

20.1.17.2 Changelog

Daml.Finance.Interface.Instrument.Swap.V0

Version 1.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Swap

Version 0.4.0

Update of SDK version and dependencies.

The *InstrumentKey* is extended by the *HoldingStandard* field.

The *Remove* choice was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *I*.

Added support for SOFR style rates (via a compounded index) to the interest rate swap and the asset swap.

Extended the asset swap to support a basket of underlyings.

Version 0.3.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factories returns the corresponding interface (rather than the base instrument interface).

Added *GetView* choice to all instrument interfaces.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asBaseInstrument* methods were removed).

Version 0.2.1

Updates to data types related to interest rate compounding and payment lag.

Updates to data types related to Term period.

20.1.18 Daml.Finance.Interface.Instrument.Token.V4

This package contains the *interface* definitions for simple token instruments which do not define any lifecycling logic. It contains the following modules:

Instrument: Instrument interface for simple tokens

Factory: Factory interface to instantiate simple tokens

Types: Type definitions to support simple tokens

Check out the [Transfer tutorial](#) for an example on how to create a simple token instrument and use it for a transfer.

20.1.18.1 Changelog

20.1.18.2 Changelog

Daml.Finance.Interface.Instrument.Token.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Token

Version 3.0.0

Update of SDK version and dependencies.

The *InstrumentKey* is extended by the *HoldingStandard* field.

The *Remove* choice was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *I*.

Version 2.0.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factory returns the corresponding interface (rather than the base instrument interface).

Make use of the *requires* keyword to enforce the interface hierarchy (in the particular *asDisclosure* and *asBaseInstrument* implementations were removed).

20.1.19 Daml.Finance.Interface.Instrument.Types.V2

This package contains types shared by several instruments. It contains the following modules:

FloatingRate: Types used to specify different kinds of floating reference rates.

20.1.19.1 Changelog

20.1.19.2 Changelog

Daml.Finance.Interface.Instrument.Types.V2

Version 2.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Interface.Instrument.Types

Version 1.0.0

First release.

20.2 Implementation Packages

This section lists the implementation packages contained within Daml Finance:

20.2.1 Daml.Finance.Holding.V4

This package contains the *implementation* of holdings, including utility functions. It has the following modules:

Fungible: Implementation of a holding which is fungible only, i.e., include split and merge functionality

Transferable: Implementation of a holding which is transferable only

TransferableFungible: Implementation of a holding which is both transferable and fungible

BaseHolding: Implementation of a holding which is neither transferable nor fungible

Util: Utility functions related to holdings, e.g., to transfer or split/merge a holding

The [Asset Model](#) page explains the relationship between instruments, holdings, and accounts. Also, check out the [Transfer tutorial](#) for a description of how to create a holding on an instrument and transfer it between accounts.

20.2.1.1 Changelog

20.2.1.2 Changelog

Daml.Finance.Holding.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Holding

Version 3.0.1

Resolved an issue in the *Daml.Finance.Holding.V4* package affecting the *Disclosure.I* implementation of the *Factory* template within the *Daml.Finance.Holding.V4.Factory* module. This patch ensures that observers are now correctly updated for the associated *Reference* template.

Version 3.0.0

Update of SDK version and dependencies.

Added an *id : Id* field to the *Factory*.

Replaced all factories by a single *Factory* for all holding implementations.

Added an assert that the *custodian* remains the same for both the sending and receiving accounts.

Removed the consistence check that credited and debited holdings must have the same *templateTypeRep*. They now need to have the same *HoldingStandard* (but can have different implementations).

Added a *Fungible* implementation, and renamed the *NonTransferable* and *Fungible* implementations to *BaseHolding* and *TransferableFungible*, respectively.

The holding implementations newly ensure that the desired *HoldingStandard* is met.

The locking logic was factored out to a separate *Lockable* interface (within the *Daml.Finance.Interface.Util.V3* package), and the *acquireImpl* and *releaseImpl* utility functions moved to the *Lockable* module in the *Daml.Finance.Util.V4* implementation package.

The *Transfer*, *Split*, *Merge*, and *Debit* actions on holdings are prohibited in a locked state, requiring them to be unlocked first. Notably, the type signatures for *splitImpl* and *mergeImpl* have been modified, and the re-entrant lock logic of *transferImpl* removed.

Renamed the *F* type synonym to *T*.

Version 2.0.0

Update of SDK version and dependencies.

Remove implementation of *Remove* choice from factory templates.

Added default *splitImpl* and *mergeImpl* for *Fungible* to *Util.daml*.

Generalized the *acquireImpl* and *releaseImpl* to not rely on an attribute called `lock`.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure*, *asBase*, and *asTransferable* implementations were removed).

The *Transfer* choice of the *Transferable* interface now includes the new owner as a choice observer.

Implementation of *Lockable* does not allow an empty *lockers* set.

Version 1.0.2

Dependencies update.

Version 1.0.1

Fix bug in the implementation of *Fungible.Merge*.

Improve error message when acquiring a lock.

20.2.2 Daml.Finance.Account.V4

This package contains the *implementation* of accounts. It has the following module:

Account: Implementation of an account, i.e., a relationship between a custodian and an asset owner, referenced by holdings. It also provides an implementation of a factory from which you can create and remove accounts. Upon creation of an account, it allows you to specify controlling parties for incoming / outgoing transfers.

20.2.2.1 Changelog

20.2.2.2 Changelog

Daml.Finance.Account.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Account

Version 3.0.0

Update of SDK version and dependencies.

The Account now uses a key (specifically, a *HoldingFactoryKey*) to reference its *Daml.Finance.Interface.Holding.V4.Factory*, rather than a *ContractId*.

The Remove implementation was removed from the *Factory* (it is newly part of the *Account* interface).

The *Account* has been enhanced to implement the *Lockable* interface with the *custodian* as required authorizer for executing the *Acquire* choice (an alternative implementation that does not utilize *Lockable* remains viable).

Version 2.0.0

Update of SDK version and dependencies.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* implementation was removed).

Use *ensure* to ensure that the set of outgoing controllers is non-empty.

Version 1.0.1

Dependencies update.

20.2.3 Daml.Finance.Settlement.V4

This package contains the *implementation* of the components used for settlement. It has the following modules:

RouteProvider.SingleCustodian: Used to generate a single *RoutedStep* from a *Step* using a single custodian

RouteProvider.IntermediatedStatic: Used to generate a route, i.e., *RoutedSteps*, for each settlement Step

Instruction: Used to settle a single *RoutedStep*, i.e., a *Step* at a custodian.

Batch: Allows you to atomically settle a set of settlement *Instructions*

Factory: Used to create a set of settlement *Instructions*, and a *Batch* to atomically settle them

Hierarchy: Data type that describes a hierarchical account structure between multiple parties

The [Settlement](#) page contains an overview of the settlement process and explains the relationship between `Instruction` and `Batch`. Also, check out the [Settlement tutorial](#) for a description on how to implement the settlement workflow in practice.

20.2.3.1 Changelog

20.2.3.2 Changelog

Daml.Finance.Settlement.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Settlement

Version 3.0.0

Update of SDK version and dependencies.

Removed the check for consistent settled holdings. Now, holdings of the same instrument don't need identical `templateTypeRep`, instead they should share the same token standard (implementation variations are allowed).

For the `Batch` and `Instruction` templates, the `requestors : Parties` field got split up into an `instructor : Party` as maintainer of the `Instruction` key, and `consenters : Parties` as additional signatories.

Version 2.0.0

Update of SDK version and dependencies.

In the settlement `Factory`, the id values used for the `Instruction`s` were modified to accurately reflect their order within the `Batch`.

In the `Batch`, the order of the `settledCids` were changed to match the initial order of the instructions in the batch.

Bug fix: replace `groupOn` by `sortAndGroupOn` in the `Instruction` and `IntermediatedStatic` templates. Lock pledged holding when allocating to an `Instruction`: the pledged holding is locked to the instruction's requestors and the outgoing controllers of the sending account.

Make use of the `requires` keyword to enforce the interface hierarchy (in particular the `asDisclosure` implementation was removed).

When an `Allocation` (resp. `Approval`) takes place, a check has been added to ensure that either the sender or the custodian (resp. the receiver or the custodian) is among the choice authorizers. When reallocation (resp. re-approval) occurs, it is required that the `signedSenders` (resp. `signedReceivers`) of the `Instruction` are part of the authorizing set.

Add additional checks to the pass-through allocation/approval process. Specifically, verify that the specified pass-through `Instruction` is actually part of the `Batch`. These checks detect settlement failures during the allocation/approval stage rather than waiting until settlement occurs.

Removed the `key` from the `Batch` implementation.

Version 1.0.2

Dependencies update.

Version 1.0.1

Additional sanity checks added to *Instruction*.

20.2.4 Daml.Finance.Lifecycle.V4

This package contains the *implementation* of lifecycle related processes. It contains the following modules:

Effect: A contract encoding the *consequences* of a *lifecycle* event for one unit of the target instrument

Election: Implementation of elections (e.g. the exercise of an option) for claim based instruments

ElectionEffect: A contract encoding the *consequences* of an *election* for one unit of the target instrument

Rule.Claim: Rule contract that allows an actor to process/claim effects, returning settlement instructions

Rule.Distribution: Rule contract that defines the distribution of units of an instrument for each unit of a target instrument (e.g. share or cash dividends)

Rule.Replacement: Rule contract that defines the replacement of units of an instrument with a basket of other instruments (e.g. stock merger)

Rule.Util: Utility functions to net, split and merge pending payments

Event.Distribution: Event contract for the distribution of units of an instrument for each unit of a target instrument (e.g. share or cash dividends)

Event.Replacement: Event contract for the replacement of units of an instrument with a basket of other instruments (e.g. stock merger)

Check out the [Lifecycling tutorial](#) for a description on how lifecycling works in practice, including how to [Claim](#) an [Effect](#). There is also the tutorial [How to implement a Contingent Claims-based instrument](#), which describes how to create an [Effect](#). For a description of [Distribution](#) and [Replacement](#), check out the [Instrument/Equity/Test](#) folder. It demonstrates how to create and lifecycle a cash dividend, and how to handle corporate actions like mergers and stock splits.

20.2.4.1 Changelog

20.2.4.2 Changelog

Daml.Finance.Lifecycle.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Lifecycle

Version 3.0.0

Update of SDK version and dependencies.

The *Calculate* choice of the *Effect* and *ElectionEffect* now takes a quantity as argument to reflect the change in the *Effect.I* interface. The implementation of the *ClaimEffect* choice body of *Daml.Finance.Lifecycle.V4.Rule.Claim* also changed accordingly.

Replaced *lookupByKey* by an *exerciseByKey* in the *Distribution* and *Replacement* rule.

Replaced *providers : Parties* with *provider : Party* in the *Claim* rule (i.e., in the implementation only).

Version 2.0.0

Update of SDK version and dependencies.

Remove implementation of *Remove* choice from factory templates.

Move the *Election* module from the *Generic* to the *Lifecycle* package.

Election and *ElectionEffect* implement the *Disclosure* interface.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asEvent* implementations were removed).

The *Distribution* and *Replacement* lifecycle rules check that the target and procured instruments are active.

Version 1.0.1

Dependencies update.

20.2.5 Daml.Finance.Data.V4

This package implements templates containing reference data. It includes the following modules:

Numeric.Observation: An implementation of an observation that explicitly stores time-dependent numerical values on the ledger. It can be used to, e.g., store equity or rate fixings.

Reference.HolidayCalendar: A holiday calendar of an entity (typically an exchange or a currency)

Time.DateClock.Types: A date type which can be converted to time, and time-related utility functions

Time.DateClock: A contract specifying what is the current local date. It is used to inject date information in lifecycle processing rules

Time.DateClockUpdate: A contract representing passing of (market) time that can be used to trigger contractual, time-based effects, like interest payments on a bond. It is, for example, used to drive the evolution and lifecycling of *Contingent Claims*-based instruments.

Time.LedgerTime: A time observable which uses ledger time

20.2.5.1 Changelog

20.2.5.2 Changelog

Daml.Finance.Data.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Data

Version 3.0.0

Update of SDK version and dependencies.
Removed the key from the *LedgerTime* as it was unused.

Version 2.0.0

Update of SDK version and dependencies.
Remove implementation of *Remove* choice from factory templates.
Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure*, *asNumericObservable*, *asTimeObservable*, and *asEvent* implementations were removed).
Removed key from *DateClock*.

Version 1.0.1

Fixed a bug in the *DateClock* implementation to avoid key violations.
Dependencies update.

20.2.6 Daml.Finance.Claims.V3

This package contains utility functions that facilitate building and working with [Contingent Claims](#) based instruments. It includes the following modules:

[Lifecycle.Rule](#): Rule to process a lifecycle event for instruments that build a [Contingent Claims tree dynamically](#).

[Util](#): Contains utility functions for claims, e.g., checking the content of a claim and converting the claim time

[Util.Lifecycle](#): Defines different types of events and how to lifecycle them

[Util.Builders](#): Utility functions related to creating [Contingent Claims](#), e.g. for bonds/swaps

[Util.Date](#): Utility functions related to dates and schedule periods, which are used to define claims.

20.2.6.1 Changelog

20.2.6.2 Changelog

Daml.Finance.Claims.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Claims

Version 2.1.0

Update of SDK version and dependencies.

Added builder function for SOFR style rates (via a compounded index).

Version 2.0.0

Update of SDK version and dependencies.

The lifecycle rule supports a combination of elections and time-based events.

Improve tagging of new instrument versions in the lifecycle rule.

A new instrument version is created and returned by the *Evolve* choice also when the instrument expires.

Version 1.0.1

Dependencies update.

20.2.7 Daml.Finance.Util.V4

This package primarily contains utility functions related to dates (see the [interface docs](#) for an introduction), lists, maps, and disclosure. They are defined in the following modules:

[Date.Calendar](#): Functions regarding dates and holiday calendars (business vs non-business days)

[Date.DayCount](#): Functions to calculate day count fractions according to different conventions

[Date.RollConvention](#): Functions to calculate date periods including rolling dates

[Date.Schedule](#): Functions to calculate a periodic schedule, including both adjusted and unadjusted dates

[Common](#): Various functions related to lists and maps, which are used in several packages

[Disclosure](#): Utility functions related to disclosure, e.g., to add or remove observers

[Lockable](#): Default implementation for the locking of holdings (acquire, release and validation check).

20.2.7.1 Changelog

20.2.7.2 Changelog

Daml.Finance.Util.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.
Only release a Semaphore lock if the provided context is recognized.

Daml.Finance.Util

Version 3.1.0

Update of SDK version and dependencies.
Added a *Lockable* module containing the *acquireImpl* and *releaseImpl* locking utility functions.
Fix a bug in the schedule roll-out logic.
Added new day-count conventions: Act365NL, Basis30365, and Basis30E2360.

Version 3.0.0

Update of SDK version and dependencies.
Remove the *groupBy* utility function.

Version 2.0.0

calcPeriodDcf and *calcPeriodDcfActActISMA* take a *ScheduleFrequency* instead of a *Frequency*.
Dependencies update.

20.2.8 ContingentClaims.Lifecycle.V3

This package contains the *implementation* of utility functions to lifecycle a [Contingent Claims](#) tree. The following modules are included:

Lifecycle: Functions to lifecycle a [Contingent Claims](#) tree

Util: Utility functions to query a [Contingent Claims](#) tree for certain properties

20.2.8.1 Changelog

20.2.8.2 Changelog

ContingentClaims.Lifecycle.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.
Bumps *daml-ctl* to 2.5.0.

ContingentClaims.Lifecycle

Version 2.0.1

Update of SDK version and dependencies.

Version 2.0.0

Update of SDK version and dependencies.
Refactor *exercise* to identify the elected sub-tree by a textual tag rather than the actual sub-tree.

20.2.9 ContingentClaims.Valuation.V0

This package contains the *implementation* of utility functions to map a *Contingent Claims* tree into a mathematical representation to facilitate integration with pricing and risk frameworks. The following modules are included:

Stochastic: Utilities to map a *Contingent Claims* tree to a stochastic process representation

MathML: Typeclass definition to map an expression in the MathML presentation format

20.2.9.1 Changelog

20.2.9.2 Changelog

ContingentClaims.Valuation.V0

Version 0.3.0

Update of SDK version and dependencies. LF protocol update to support SCU.
Bumps *daml-ctl* to 2.5.0.

ContingentClaims.Valuation

Version 0.2.2

Update of SDK version and dependencies.

Version 0.2.1

Update of SDK version and dependencies.

20.2.10 Daml.Finance.Instrument.Bond.V3

This package contains the *implementation* of different bond types, defined in the following modules:

- Callable.Instrument*: Instrument implementation for callable bonds
- Callable.Factory*: Factory implementation to instantiate callable bonds
- FixedRate.Instrument*: Instrument implementation for fixed-rate bonds
- FixedRate.Factory*: Factory implementation to instantiate fixed-rate bonds
- FloatingRate.Instrument*: Instrument implementation for floating-rate bonds
- FloatingRate.Factory*: Factory implementation to instantiate floating-rate bonds
- InflationLinked.Instrument*: Instrument implementation for inflation-linked bonds
- InflationLinked.Factory*: Factory implementation to instantiate inflation-linked bonds
- ZeroCoupon.Instrument*: Instrument implementation for zero-coupon bonds
- ZeroCoupon.Factory*: Factory implementation to instantiate zero-coupon bonds
- Util*: Bond-specific utility functions

Check out the page on [How to use the Bond Instrument packages](#) for a description of how to use these instruments in practice. There is also the tutorial [How to implement a Contingent Claims-based instrument](#), which describes how the claims are defined and how the lifecycle interface is implemented for bonds.

20.2.10.1 Changelog

20.2.10.2 Changelog

Daml.Finance.Instrument.Bond.V3

Version 3.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Instrument.Bond

Version 2.0.0

Update of SDK version and dependencies.

Added a *HoldingStandard* field to the implementation.

The *Remove* implementation was removed from the *Factory* (it is newly part of the *Base instrument* interface).

Renamed the *F* type synonym to *T*.

Added support for SOFR style rates (via a compounded index) to the floating rate bond.

Version 1.0.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factories returns the corresponding interface (rather than the base instrument interface).

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asBaseInstrument* implementations were removed).

Introduce a new callable bond instrument.

Add a *notional* field to all instruments.

Version 0.2.1

Dependencies update.

20.2.11 Daml.Finance.Instrument.Equity.V0

This package contains the *implementation* of equity instruments, defined in the following modules:

Instrument: Instrument implementation for equities

Factory: Factory implementation to instantiate equities

For a detailed explanation of this package, check out the page on [How to use the Equity Instrument packages](#). It demonstrates how to originate an equity instrument, how to create and lifecycle a cash dividend, and how to handle corporate actions like mergers and stock splits.

20.2.11.1 Changelog

20.2.11.2 Changelog

Daml.Finance.Instrument.Equity.V0

Version 0.5.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Instrument.Equity

Version 0.4.0

Update of SDK version and dependencies.

Added a *HoldingStandard* field to the implementation.

The *Remove* implementation was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *T*.

Version 0.3.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factory returns the corresponding interface (rather than the base instrument interface).

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asBaseInstrument* implementations were removed).

Rename *DeclareDividend* to *DeclareDistribution*.

Version 0.2.1

Dependencies update.

20.2.12 Daml.Finance.Instrument.Generic.V4

This package contains the *implementation* of generic, [Contingent Claims](#) based instruments, defined in the following modules:

[Instrument](#): Instrument implementation for generic instruments

[Factory](#): Factory implementation to instantiate generic instruments

[Lifecycle.Rule](#): Rule to process a lifecycle event for generic instruments

Check out the page on [How to use the Generic Instrument packages](#) as well as the [Payoff modeling tutorial](#) to learn how to use this instrument in practice.

20.2.12.1 Changelog

20.2.12.2 Changelog

Daml.Finance.Instrument.Generic.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Instrument.Generic

Version 3.0.0

Update of SDK version and dependencies.

Added a *HoldingStandard* field to the implementation.

The *Remove* implementation was removed from the *Factory* (it is newly part of the *Base instrument* interface).

Renamed the *F* type synonym to *T*.

Version 2.0.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factory returns the corresponding interface (rather than the base instrument interface).

Move the *Election* module to the *Lifecycle* package. Also, refactor the *Election* to identify the elected sub-tree by a textual tag rather than the actual sub-tree.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure*, *asBaseInstrument*, and *asClaim* implementations were removed).

A new instrument version is created and returned by the lifecycle rule choice also when the instrument expires.

Version 1.0.1

Dependencies update.

20.2.13 Daml.Finance.Instrument.Option.V0

This package contains the *implementation* of different option types, defined in the following modules:

[*BarrierEuropeanCash.Instrument*](#): Instrument implementation for barrier options

[*BarrierEuropeanCash.Factory*](#): Factory implementation to instantiate barrier options

[*Dividend.Instrument*](#): Instrument implementation for dividend options

[*Dividend.Factory*](#): Factory implementation to instantiate dividend options

[*Dividend.Election*](#): Factory implementation to create an Election for dividend options

[*EuropeanCash.Instrument*](#): Instrument implementation for cash-settled European options

[*EuropeanCash.Factory*](#): Factory implementation to instantiate cash-settled European options

[*EuropeanPhysical.Instrument*](#): Instrument implementation for physically settled European options

[*EuropeanPhysical.Factory*](#): Factory implementation to instantiate physically settled European options

Check out the page on [How to use the Option Instrument packages](#) for a description of how to use the these instruments in practice.

20.2.13.1 Changelog

20.2.13.2 Changelog

Daml.Finance.Instrument.Option.V0

Version 0.4.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Instrument.Option

Version 0.3.0

Update of SDK version and dependencies.

Added a *HoldingStandard* field to the implementation.

The *Remove* implementation was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *T*.

Removed the *Remove* choice from the election factory.

Version 0.2.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factories returns the corresponding interface (rather than the base instrument interface).

Add instruments physically-settled European options, dividend options, barrier options.

Renamed cash-settled European options to *EuropeanCash*.

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asBaseInstrument* implementations were removed).

20.2.14 Daml.Finance.Instrument.StructuredProduct.V0

This package contains the *implementation* of different structured product types, defined in the following modules:

AutoCallable.Instrument: Instrument implementation for Auto Callables

AutoCallable.Factory: Factory implementation to instantiate Auto Callables

BarrierReverseConvertible.Instrument: Instrument implementation for Barrier Reverse Convertibles

BarrierReverseConvertible.Factory: Factory implementation to instantiate Barrier Reverse Convertibles

Check out the page on [How to use the Structured Products package](#) for a description of how to use the these instruments in practice.

20.2.14.1 Changelog

20.2.14.2 Changelog

Daml.Finance.Instrument.StructuredProduct.V0

Version 0.2.0

Update of SDK version and dependencies. LF protocol update to support SCU.
New AutoCallable instrument.

Daml.Finance.Instrument.StructuredProduct

Version 0.1.0

First release.

20.2.15 Daml.Finance.Instrument.Swap.V0

This package contains the *implementation* of different swap types, defined in the following modules:

- Asset.Instrument*: Instrument implementation for asset swaps
- Asset.Factory*: Factory implementation to instantiate asset swaps
- CreditDefault.Instrument*: Instrument implementation for credit default swaps
- CreditDefault.Factory*: Factory implementation to instantiate credit default swaps
- Currency.Instrument*: Instrument implementation for currency swaps
- Currency.Factory*: Factory implementation to instantiate currency swaps
- ForeignExchange.Instrument*: Instrument implementation for foreign exchange swaps
- ForeignExchange.Factory*: Factory implementation to instantiate foreign exchange swaps
- Fpml.Instrument*: Instrument implementation for FpML swaps ([FpML swap schema](#))
- Fpml.Factory*: Factory implementation to instantiate FpML swaps
- Fpml.Util*: Utility functions to support FpML swaps
- InterestRate.Instrument*: Instrument implementation for interest rate swaps
- InterestRate.Factory*: Factory implementation to instantiate interest rate swaps

Check out the page on [How to use the Swap Instrument packages](#) for a description of how to use these instruments in practice.

20.2.15.1 Changelog

20.2.15.2 Changelog

Daml.Finance.Instrument.Swap.V0

Version 0.5.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Instrument.Swap

Version 0.4.0

Update of SDK version and dependencies.

Added a *HoldingStandard* field to the implementation.

The *Remove* implementation was removed from the *Factory* (it is newly part of the *Base* instrument interface).

Renamed the *F* type synonym to *T*.

Added support for SOFR style rates (via a compounded index) to the interest rate swap and the asset swap.

Extended the asset swap to support a basket of underlyings.

Added a dedicated asset swap *DistributionRule* for total return swaps that pay dividends separately from the asset performance.

Version 0.3.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factories returns the corresponding interface (rather than the base instrument interface).

Make use of the *requires* keyword to enforce the interface hierarchy (in particular the *asDisclosure* and *asBaseInstrument* implementations were removed).

FpmlSwap now accepts a non-zero rate fixing lag.

Version 0.2.1

Implement interest rate compounding (several calculation periods per payment period).

Support a more generic way of specifying notional step schedules.

Support specification of a payment lag.

Efficient calculation of SOFR-like daily compounded reference rates.

Implement arrears reset.

Implement step-up coupon.

Add support for initial stub period that starts before the issue date of the swap.

Improve handling of principal exchange.

Add support for Term period of a swap leg.

Additional improvements required to make the official FpML trades 1..7 work as expected.

20.2.16 Daml.Finance.Instrument.Token.V4

This package contains the *implementation* of simple token instruments which do not define any life-cycling logic. It contains the following modules:

Instrument: Instrument implementation for simple tokens

Factory: Factory implementation to instantiate simple tokens

Check out the [Transfer tutorial](#) for an example on how to create a simple token instrument and use it for a transfer.

20.2.16.1 Changelog

20.2.16.2 Changelog

Daml.Finance.Instrument.Token.V4

Version 4.0.0

Update of SDK version and dependencies. LF protocol update to support SCU.

Daml.Finance.Instrument.Token

Version 3.0.0

Update of SDK version and dependencies.

Added a *HoldingStandard* field to the implementation.

The *Remove* implementation was removed from the *Factory* (it is newly part of the *Base instrument* interface).

Renamed the *F* type synonym to *T*.

Version 2.0.0

Update of SDK version and dependencies.

The *Create* choice on the instrument factory returns the corresponding interface (rather than the base instrument interface).

Make use of the *requires* keyword to enforce the interface hierarchy (in the particular *asDisclosure* and *asBaseInstrument* implementations were removed).

Version 1.0.1

Dependencies update.

Chapter 21

Tutorials

This section contains step-by-step implementation guides across different aspects of the Daml Finance library.

21.1 Getting Started

This section explains how some key concepts of Daml Finance work in practice. It combines a step by step description of different workflows with supporting Daml code.

The following tutorials are available:

Holdings: describes the core asset model used in Daml Finance.

Transfer: shows how to transfer ownership of a holding to another party.

Settlement: explains how to execute multiple asset movements atomically.

Lifecycle: describes how lifecycle rules and events can be used to evolve instruments over time.

Each tutorial builds on top of the previous ones, so they should ideally be followed in order.

21.1.1 Prerequisites

We expect the reader to be familiar with the basic building blocks of Daml. If that is not the case, a suitable introduction can be found [here](#).

An understanding of [Daml Interfaces](#) is very helpful, as these are used extensively throughout the library. However, you should be able to follow along and grasp the fundamental concepts also without detailed knowledge on interfaces.

Finally, make sure that the [Daml SDK](#) is installed on your machine.

21.1.2 Download the Code for the Tutorials

Open a new terminal window and run:

```
daml new quickstart-finance --template quickstart-finance
```

This creates a new folder with contents from our template. Navigate to the folder and then run the following to download the required Daml Finance packages:

```
./get-dependencies.sh
```

or, if you are using Windows

```
./get-dependencies.bat
```

Finally, you can start Daml Studio to inspect the code and run the project's scripts:

```
daml studio
```

21.1.3 Structure of the Code and Dependencies

The project includes

- four workflows defined in the `Workflows` folder
- four Daml scripts defined in the `Scripts` folder

The `Workflows` encapsulate the core business logic of the application, whereas the `Scripts` are meant to be executed on a one-off basis.

As you can see from the import list, modules in the `Workflows` folder depend only on *interface* packages of Daml Finance (the packages that start with `Daml.Finance.Interface.*`).

This is important, as it decouples the user-defined business logic from the template implementations used in Daml Finance, which makes it easier to upgrade the application. The user-defined business logic in the `Workflows` will not need to be modified nor re-compiled to work with upgraded (ie., newer versions of) *implementation* packages.

On the other hand, modules in the `Scripts` folder depend on both the *interface* packages and the *implementation* packages (in this case, `Daml.Finance.Account.V4`, `Daml.Finance.Holding.V4`, and `Daml.Finance.Instrument.Token.V4`). This is not problematic as scripts are meant to be run only once when the application is initialized.

21.1.4 Holdings

This tutorial introduces the core asset model of the library through a simple example. The purpose is to illustrate the concepts of [account](#), [instrument](#), and [holding](#), as well as to show some useful patterns when working with Daml interfaces.

We are going to use the Daml Finance library to create tokenized cash on the ledger. This is done in three steps:

1. we first create accounts for Alice and Bob at the Bank
2. we then proceed to issue a cash instrument, representing tokenized dollars
3. we finally credit a cash holding to Alice's account

The holding contract represents the record of ownership on the ledger for Alice's tokenized cash.

21.1.4.1 Run the script

In order to show how this works in practice, let us explore the `Holding` script step-by-step.

Create Account, Holding, and Instrument Factories

The first instruction instantiates an account factory. This is a template that is used by a party (the Bank in this case) to create accounts as part of the `CreateAccount` workflow.

```
accountFactoryCid <- toInterfaceContractId @AccountFactory.I <$> submit bank do
  createCmd Account.Factory with
    provider = bank
    observers = mempty
```

Notice how the `ContractId` is immediately converted to an interface upon creation: this is because our workflows, such as `CreateAccount`, do not have any knowledge of concrete template implementations.

Similarly, we instantiate a *holding factory*, which is used within an account to create (Credit) holdings for any instrument.

```
holdingFactory <- createHoldingFactory
  Holding.Factory with
    provider = bank
    id = Id "Holding Factory"
    observers = Map.fromList [("Settlers", Set.fromList [alice, bob])]
```

Finally, we create a factory template which is used to instantiate *token instruments*.

```
tokenFactoryCid <- toInterfaceContractId @TokenFactory.I <$> submit bank do
  createCmd Token.Factory with
    provider = bank
    observers = mempty
```

Open Alice's and Bob's Accounts

Once the factory templates are setup, we leverage the `CreateAccount` workflow to create accounts at the Bank for Alice and Bob.

The creation of an account needs to be authorized by both Alice and the Bank. Authorization is collected using a propose / accept pattern.

```
aliceRequestCid <- submit alice do
  createCmd CreateAccount.Request with
    owner = alice
    custodian = bank

aliceAccount <- submit bank do
  exerciseCmd aliceRequestCid CreateAccount.Accept with
    label = "Alice@Bank"
```

(continues on next page)

(continued from previous page)

```

description = "Account of Alice at Bank"
accountFactoryCid -- This is equivalent to writing accountFactoryCid =  

↳accountFactoryCid
holdingFactory
observers = []

```

The Bank acts as the custodian, or account provider, whereas Alice is the account owner. Bob's account is created in a similar fashion.

Create the Cash Instrument

In order to credit Alice's account with some cash, we first create a cash instrument. An instrument is a representation of what it is that we are holding against the Bank. It can be as simple as just a textual label (like the *Token Instrument* used in this case) or it can include complex on-ledger lifecycling logic.

```

let
  instrumentId = Id "USD"
  instrumentVersion = "0"
  instrumentKey = InstrumentKey with
    issuer = bank
    depository = bank
    id = instrumentId
    version = instrumentVersion
    holdingStandard = TransferableFungible
now <- getTime

submit bank do
  exerciseCmd tokenFactoryCid TokenFactory.Create with
    token = Token with
      instrument = instrumentKey
      description = "Instrument representing units of a generic token"
      validAsOf = now
      observers = mempty

```

Notice how in this case the Bank acts both as the issuer and depository of the cash instrument. This means that we fully trust the Bank with any action concerning the instrument contract.

Deposit Cash in Alice's Account

We can now deposit cash in Alice's account, using the *CreditAccount* workflow. Alice creates a request to deposit USD 1000 at the Bank, the Bank then accepts the request and a corresponding *Holding* is created.

```

aliceRequestCid <- submit alice do
  createCmd CreditAccount.Request with
    account = aliceAccount
    instrument = instrumentKey
    amount = 1000.0

aliceCashHoldingCid <- submit bank do exerciseCmd aliceRequestCid CreditAccount.
↳Accept

```

You can imagine that the latter step happens only after Alice has shown up at the Bank and delivered physical banknotes corresponding to the amount of the deposit.

The holding contract represents the record of ownership on the ledger. In this scenario, Alice's holding of 1000 units of the cash instrument means that she is entitled to claim USD 1000 from holding's custodian, the Bank.

To summarize

- an instrument defines *what* a party holds (the rights and obligations).
- a holding defines *how much* (i.e., the amount) of an instrument and *against which party* (i.e., the custodian) the instrument is being held.

21.1.4.2 Frequently Asked Questions

What are accounts used for?

An account is used as the proof of a business relationship between an owner and a custodian: Alice may transfer cash to Bob because Bob has a valid account at the Bank.

This is done to avoid that Alice transfers cash to Charlie without Charlie being vetted and acknowledged by the Bank.

The account is also used to determine who is required to authorize incoming and outgoing transfers. For the account at hand, the owner acts as a controller for both incoming and outgoing transfers. The other options are explained as part of the settlement tutorials.

Why do we need factories?

You might be wondering why we use account factories and holding factories instead of creating an [Account](#) or [Holding](#) directly.

This is done to avoid having to reference the `Daml.Finance.Holding.V4` package directly in the user workflows (and hence simplify upgrading procedures).

This pattern is described in detail in the [Daml Finance Patterns](#) page and is based on the assumption that there are very few factory contracts which are setup on ledger initialization.

21.1.4.3 Summary

You now know how to setup basic accounts, holdings, and instruments. The key concepts to take away are:

- Holdings represent the ownership of a financial instrument at a custodian.
- Instruments define the economic terms of a financial contract.
- Accounts ensure that only known parties can obtain ownership.
- Factories are used to create the respective contracts without having to depend on implementation packages.

21.1.5 Transfer

This tutorial builds on the previous chapter, which introduced [account](#), [instrument](#), and [holding](#).

We are now going to transfer the holding that we created in the previous tutorial from Alice to Bob.

21.1.5.1 Run the Script

Let us now explore the `Transfer` script step-by-step. It builds on the previous [Holdings](#) tutorial script in the sense that the same accounts and the existing holdings are used.

Transfer Cash from Alice to Bob

The final step of our `Setup` script transfers Alice's holding to Bob using the `Transfer` workflow. In our tutorial example, the receiver of the cash makes the transfer request:

```
transferRequestCid <- submit bob do
  createCmd Transfer.Request with
    receiverAccount = bobAccount
    instrument = cashInstrument
    amount = 1000.0
    currentOwner = alice

bobCashHoldingCid <- submit alice do
  exerciseCmd transferRequestCid Transfer.Accept with holdingCid =
    ↪aliceCashHoldingCid
```

Bob requests the cash to be transferred to his account. Alice then accepts the request.

21.1.5.2 Frequently Asked Questions

How does the `Transfer` workflow work?

If you look at the implementation of the `Transfer` workflow, you will notice the following lines:

```
let transferableCid = coerceInterfaceContractId @Transferable.I holdingCid

newTransferableCid <- exercise transferableCid Transferable.Transfer with
  actors = fromList [currentOwner, receiverAccount.owner]
  newOwnerAccount = receiverAccount

pure $ toInterfaceContractId @Holding.I newTransferableCid
```

The first line converts the holding contract id (of type [ContractId Holding.I](#)) to the [Transferable.I](#) interface using `coerceInterfaceContractId`.

Then, the `Transfer` choice, defined as part of the [Transferable](#) interface, is exercised.

Finally, the new holding is converted back to a [Holding.I](#) before it is returned. This is done using `toInterfaceContractId`.

In order to fully understand these instructions, we need to keep in mind the interface hierarchy used by our holding implementation.

We use `coerceInterfaceContractId` to convert the [Holding.I](#) to a [Transferable](#). The success of this operation is not guaranteed and will result in a run-time error if the holding implementation at hand does not implement [Transferable](#).

We use `toInterfaceContractId` to convert back to a [Holding](#). This is because all [Transferables](#) implement the [Holding.I](#) interface, so the validity of this operation is guaranteed at compile-time.

Why is Alice an observer on Bob's account?

You might have noticed that Alice is an observer of Bob's account and you might be wondering why this is the case.

This is because the party exercising the `Transfer` choice, which in this case is Alice, needs to fetch Bob's account in order to verify that it has not been archived.

If we wanted to avoid Bob's account contract ever being disclosed to Alice, we would need a third party (in this case the Bank) to execute the `Transfer`.

21.1.5.3 Exercises

There are a couple of improvements to the code that can be implemented as an exercise. They will help you familiarize yourself with the library and with Daml interfaces.

Split the Holding to Transfer the Right Amount

In the example, Bob requests `USD 1000` from Alice and Alice allocates a holding for exactly the right amount, because the transfer would otherwise fail. We want the transfer to be successful also if Alice allocates a holding for a larger amount e.g., `USD 1500`.

We can leverage the fact that the holding implements the [Fungible](#) interface, which makes it possible to `Split` it into a holding of `USD 1000` and one of `USD 500`. In the implementation of the `CashTransferRequest_Accept` choice:

- cast the allocated holding to the [Fungible](#) interface
- use the `Split` choice to split the larger holding into two holdings
- execute the transfer, allocating the holding with the correct amount

In the last step, you will need to cast the [Fungible](#) to a [Transferable](#) using `toInterfaceContractId`.

Temporary Account Disclosure

There is no reason for Alice to be an observer on Bob's account before the transfer is initiated by Bob (and after the transfer is executed).

Modify the original code, such that:

```
Bob's account is disclosed to Alice once the transfer is initiated
When the Transfer is executed, Alice removes herself from the account observers
```

In order to do that, you can leverage the fact that [Account](#) implements the [Disclosure](#) interface. This interface exposes the `AddObservers` and `RemoveObservers` choices, which can be used to disclose / undisclose Bob's account contract to Alice. In order to exercise these choices, you can use the [Account.exerciseInterfaceByKey](#) utility function.

21.1.5.4 Summary

You now learned how to perform a simple transfer. The key concepts to take away are:

```
Holdings represent the ownership of a financial instrument at a custodian.
Transfers change ownership of a holding.
```

Ownership transfers typically happen as part of a larger financial transaction. The next tutorial will show you how to create such a transaction and how to settle it atomically.

21.1.6 Settlement

This tutorial introduces the settlement features of the library through a simple example. The purpose is to demonstrate how multiple holding transfers can be executed atomically.

We are going to:

1. create a new `TOKEN` [instrument](#)
2. credit a `TOKEN` holding to Alice's account
3. setup a delivery-vs-payment (DvP) transaction to give Alice's `TOKEN` holding to Bob in exchange for a `USD` holding
4. settle this transaction atomically

This example builds on the previous [Transfer](#) tutorial script in the sense that the same accounts and the existing holdings are used.

21.1.6.1 Overview of the Process

We first give a quick outline of the settlement process:

1. Define steps to be settled	Two (or more) parties need to first agree on a set of steps to be settled.
2. Generate settlement instructions	Instructions are generated for each step. An instruction is a contract where the sender can specify its Allocation preference for the instruction (e.g., the matching holding they wish to send). The receiver can specify its Approval preference for the instruction (e.g., the account they wish to receive the holding to). The creation of Instructions is done by first using a Route Provider and then applying a Settlement Factory .
3. Allocate and approve instructions	For every instruction, the sender and the receiver specify their allocation and approval preferences, respectively.
4. Settle the batch	A Batch contract is used to settle all instructions atomically according to the specified preferences (e.g. by transferring all allocated holdings to the corresponding receiving accounts). This batch contract is created in step 2, together with the settlement instructions.

21.1.6.2 Run the Script

The code for this tutorial can be executed via the `runSettlement` function in the `Settlement.daml` module.

The first part executes the script from the previous [Transfer](#) tutorial to arrive at the initial state for this scenario. We then create an additional `TOKEN` [instrument](#) and credit Alice's account with it.

The interesting part begins once Bob proposes the DvP trade to Alice. Before creating the DvP proposal, we need to instantiate two contracts:

1. [Route Provider](#)

```
routeProviderCid <- toInterfaceContractId @RouteProvider.I <$> submit bank
→do
  createCmd SingleCustodian with
    provider = bank; observers = fromList [alice, bob]; custodian = bank
```

This is used to discover a settlement route, i.e., [routed steps](#), for each settlement [step](#). In this example, the route provider simply converts each step to a routed step using a single custodian (the bank).

2. [Settlement Factory](#)

```
settlementFactoryCid <- toInterfaceContractId @SettlementFactory.I <$>
→submit bank do
  createCmd Settlement.Factory with
    provider = bank
    observers = fromList [alice, bob]
```

This is used to generate the settlement batch and instructions from the [routed steps](#).

Bob creates a `Dvp.Proposal` template to propose the exchange of the `TOKEN` against `USD`.

```

dvpProposalCid <- submit bob do
  createCmd DvP.Proposal with
    id = "xccy trade"
    recQuantity = qty 10.0 tokenInstrument
    payQuantity = qty 1000.0 usdInstrument
    proposer = bob
    counterparty = alice
    routeProviderCid -- This is equivalent to writing routeProviderCid =
↳routeProviderCid
    settlementFactoryCid

```

Alice then accepts the proposal, agreeing to the terms of the trade.

```

(batchCid, recSettleInstructionCid, paySettleInstructionCid) <- submit alice do
  exerciseCmd dvpProposalCid DvP.Accept

```

Once the proposal is accepted, three contracts are created:

- an instruction to transfer 10 TOKEN from Alice to Bob
- an instruction to transfer USD 1000 from Bob to Alice
- a batch contract to settle the two instructions atomically

The workflow to create these contracts makes use of the route provider and the settlement factory.

```

(containerCid, [recInstructionCid, payInstructionCid]) <-
  exercise settlementFactoryCid SettlementFactory.Instruct with
    instructor = proposer
    consenters = singleton counterparty
    settlers = singleton proposer
    id = Id id
    description = "Settlement for " <> id
    contextId = None
    routedSteps
    settlementTime = None -- i.e., immediate settlement

```

As a next step, Alice allocates her TOKEN holding to the corresponding instruction. Bob then approves the instruction specifying the receiving account.

```

(allocatedRecSettleInstructionCid, _) <- submit alice do
  exerciseCmd recSettleInstructionCid Instruction.Allocate with
    actors = singleton alice
    allocation = Pledge aliceHoldingCid

approvedRecSettleInstructionCid <- submit bob do
  exerciseCmd allocatedRecSettleInstructionCid Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount

```

The same happens in the second instruction (where Bob allocates his USD holding and Alice provides the receiving account).

Now that all instructions are fully allocated and approved, they can finally be settled.

```

[bobHoldingCid, aliceHoldingCid] <- submit bob do
  exerciseCmd batchCid Batch.Settle with
    actors = singleton bob

```

Within the same transaction, Alice receives a `USD` holding from Bob in exchange for a `TOKEN` holding.

21.1.6.3 Frequently Asked Questions

Why do we need a route provider?

Consider a real-world example where Bob instructs a bank transfer to send USD 100 to Alice. The following happens:

- USD 100 are debited from Bob's account at his bank
- USD 100 are transferred from Bob's bank to Alice's bank (via their accounts at the central bank)
- USD 100 are credited to Alice's account at her bank

A single settlement [Step](#) requires three [RoutedSteps](#) to settle.

The same dynamics can be reproduced in Daml with a [Route Provider](#) implementation, allowing for on-ledger intermediated settlement. For example, see the [Intermediated Lifecycling](#) tutorial.

Why do we need a settlement factory?

A settlement factory contract is used to generate settlement [Instructions](#) from [RoutedSteps](#). It also generates a [Batch](#) contract, which is used to settle instructions atomically.

The reason why the factory is needed has already been introduced in the previous tutorial: it provides an interface abstraction, so that your workflow does not need to depend on concrete implementations of [Batch](#) or [Instructions](#).

Can we use a different settler?

In our example, Bob triggers the final settlement of the transaction (by exercising the `Settle` choice on the [Batch](#) contract).

In principle, a different settler could be chosen. The choice of a settler is usually quite delicate, as this party acquires visibility on the entire transaction and hence needs to be trusted.

What if one party wants to cancel the settlement?

The parties who sign the [Batch](#) contract (the instructor and consenters) can exercise the `Cancel` choice of the [Batch](#) to cancel all associated [Instructions](#) atomically.

21.1.6.4 Summary

You know how to define complex transactions and settle them atomically. The main points to take away are:

- A route provider is used to discover settlement routes, i.e., routed steps, for each settlement step.

- A settlement factory is used to instruct settlement for an arbitrary list of routed steps.

- Instructions are used to collect authorizations, assets to be moved, and means of settlement.

- Batches group together instructions to be settled atomically.

In the next tutorial, we will introduce the lifecycling framework of the library, which is used to model the evolution of instruments. The concepts introduced in this tutorial will be used to settle payments arising from lifecycle events.

21.1.7 Lifecycling

This tutorial introduces the [lifecycling](#) framework of the library with a simple example. The purpose is to demonstrate how lifecycle rules and events can be used to process a dividend payment.

We are going to:

1. create a new version of the token instrument
2. create the required lifecycle rules
3. create a distribution event
4. process the event to produce the effects from the distribution
5. instruct settlement by presenting a token holding
6. settling the resulting batch atomically

This example builds on the previous [Settlement](#) tutorial script in the sense that the same accounts and the existing holdings are used.

21.1.7.1 Overview of the Process

We first give a high-level outline of the lifecycle process:

1. Create a lifecycle rule	A lifecycle rule implements the logic to calculate effects for a given lifecycle event. In our example we create a distribution rule to handle the dividend event on our token.
2. Create a lifecycle event	The lifecycle event refers to the <i>target instrument</i> the event applies to. Holdings on this instrument can then be used to claim the resulting lifecycle effect.
3. Process the event through the lifecycle rule	The lifecycle rule contains the business logic to derive the lifecycle effects resulting from a concrete event. The effect describes the per-unit holding transfers that are to be settled between a custodian and the owner of a holding.
4. Claim the effect using a holding	The claim rule is used to claim the effects resulting from a lifecycle event using a holding on the target instrument. The result is a set of settlement instructions and a corresponding batch to be settled between the custodian and the owner of the holding.

21.1.7.2 Run the Script

The code for this tutorial can be executed via the `runLifecycling` function in the `Lifecycling.daml` module.

The first part executes the script from the previous [Settlement](#) tutorial to arrive at the initial state for this scenario.

Then we create a new version of the token instrument, which is required for defining the distribution event. This is what the instrument holders will receive when processing the lifecycle event later in the tutorial.

```
let newTokenInstrument = tokenInstrument with version = "1"
now <- getTime
submit bank do
  exerciseCmd tokenFactoryCid TokenFactory.Create with
    token = Token with
      instrument = newTokenInstrument
      description = "Instrument representing units of a generic token after a
↳distribution event"
      validAsOf = now
      observers = mempty
```

Next, we create two lifecycle rules:

```
distributionRuleCid <- toInterfaceContractId @Lifecycle.I <$> submit bank do
  createCmd Distribution.Rule with
    providers = singleton bank
    lifecycler = bank
    observers = singleton bob
    id = Id "Lifecycle rule for distribution"
    description = "Rule contract to lifecycle an instrument following a
↳distribution event"
```

(continues on next page)

(continued from previous page)

```

lifecycleClaimRuleCid <- toInterfaceContractId @Claim.I <$> submit bank do
  createCmd Claim.Rule with
    provider = bank
    claimers = singleton bob
    settlers = singleton bob
    routeProviderCid
    settlementFactoryCid
    netInstructions = False

```

The [Distribution Rule](#) defines the business logic to calculate the resulting lifecycle effect from a given distribution event. It is signed by the Bank as a provider.

The [Claim Rule](#) allows a holder of the target instrument to claim the effect resulting from the distribution event. By presenting their holding they can instruct the settlement of the holding transfers described in the effect.

We then create a distribution event describing the terms of the dividend to be paid.

```

distributionEventCid <- toInterfaceContractId @Event.I <$> submit bank do
  createCmd Distribution.Event with
    providers = singleton bank
    id = Id "DISTRIBUTION"
    description = "Profit distribution"
    effectiveTime = now
    targetInstrument = tokenInstrument
    newInstrument = newTokenInstrument
    perUnitDistribution = [qty 0.02 usdInstrument]
    observers = mempty

```

Now we can process the distribution event using the distribution rule.

```

(_, [effectCid]) <- submit bank do
  exerciseCmd distributionRuleCid Lifecycle.Evolve with
    eventCid = distributionEventCid
    observableCids = []
    instrument = tokenInstrument

```

The result of this is an effect describing the per-unit asset movements to be executed for token holders. Each holder can now present their holding to *claim* the effect and instruct settlement of the associated entitlements.

```

result <- submit bob do
  exerciseCmd lifecycleClaimRuleCid Claim.ClaimEffect with
    claimer = bob
    holdingCids = [bobHoldingCid]
    effectCid -- This is equivalent to writing effectCid = effectCid
    batchId = Id "DistributionSettlement"
  let [bobInstructionCid, bankInstructionCid, couponInstructionCid] = result.
  ↪ instructionCids

```

As a side-effect of settling the entitlements, the presented holding is exchanged for a holding of the new token version. This is to prevent a holder from benefiting from a given effect twice.

In our example of a cash dividend, only a single instruction is generated: the movement of cash from the bank to the token holder. This instruction along with its batch is settled the usual way, as described in the previous [Settlement](#) tutorial.

```
-- Allocate instruction
(bobInstructionCid, _) <- submit bob do
  exerciseCmd bobInstructionCid Instruction.Allocate with
    actors = singleton bob
    allocation = Pledge bobHoldingCid

(bankInstructionCid, _) <- submit bank do
  exerciseCmd bankInstructionCid Instruction.Allocate with
    actors = singleton bank
    allocation = CreditReceiver

(couponInstructionCid, _) <- submit bank do
  exerciseCmd couponInstructionCid Instruction.Allocate with
    actors = singleton bank
    allocation = CreditReceiver

-- Approve instruction
bobInstructionCid <- submit bank do
  exerciseCmd bobInstructionCid Instruction.Approve with
    actors = singleton bank
    approval = DebitSender

bankInstructionCid <- submit bob do
  exerciseCmd bankInstructionCid Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount

couponInstructionCid <- submit bob do
  exerciseCmd couponInstructionCid Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount

-- Settle batch
submit bob do
  exerciseCmd result.batchCid Batch.Settle with actors = singleton bob
```

Note that the bank in this case does not actually transfer the cash from another account, but simply credits Bob's account by using the `CreditReceiver` allocation type. In a real-world dividend scenario one would additionally model the flow of funds from the issuer to the bank using the same lifecycle process as described above.

21.1.7.3 Frequently Asked Questions

Which party should create and sign the lifecycle rules and events?

In the simplified scenario for this tutorial, we have used the bank as both the *issuer* and *depository* for the instruments involved. In a real-world case, instruments and their corresponding lifecycle rules and events would be maintained by an actual issuer, with the depository acting as a 3rd-party trust anchor.

Which parties typically take which actions in the lifecycle workflow?

The lifecycle interfaces governing the process leave the controllers of the various choices in the process up to the implementation.

Typically, we would expect the issuer of an instrument to be responsible to generate lifecycle events (for example, announcing dividends or stock splits).

Lifecycle rules on the other hand are often controlled by 3rd-party calculation agents.

The claiming of lifecycle effects is by default the responsibility of the owner of a holding. If instead the owner wants to delegate this responsibility to their custodian they can do so via a delegation contract.

The party executing settlement can be chosen as well, as described in the previous tutorial on [Settlement](#).

Which party should take the role as *lifecycle*?

From a design perspective, a lifecycler is often the party that defines the lifecycle events happening on an instrument (although they can be different). In the simplified example above, it is the bank. In a more realistic example, it would probably be the issuer. In some special cases, if we really need the owner to be the lifecycler, we can use a delegation contract.

The lifecycler is currently trusted with:

- Timely and complete Event processing
- Providing accurate Observations

Which party is the provider of the Effect?

Most of the time the provider of the Effect is the lifecycler. However, in some cases we may want to avoid disclosing the claimed holdings to the lifecycler. The provider of the Effect gets to see all holdings claimed against that one Effect contract. If we wish to avoid that, we then need a different effect provider.

Can an instrument act as its own lifecycle rule?

Yes, an instrument can implement the `Lifecycle` interface directly such that the lifecycle rules are contained within the instrument itself. There are, however, advantages to separating this logic out into rule contracts:

Keeping lifecycle rules in a different package from your instruments allows you to independently upgrade or patch them without affecting your live instruments.

Having separate rules allows to change the lifecycle properties of an instrument dynamically at runtime. For example, an instrument can initially be created without support for doing asset distributions. Then, at a later point, the issuer might decide to start paying dividends. They can now simply add a distribution rule to the running system to enable this new lifecycle event for their instrument without affecting the actual live instrument itself (or any holdings on it).

Can I integrate a holding ownership change (of the target instrument) within lifecycling?

Lifecycling will not change the ownership of the target instrument. You should use the [Transfer](#) pattern to do a delivery-versus-payment as a separate step from the lifecycling.

However, there usually is a change of ownership of the other consumed/produced instruments when lifecycling (e.g. when paying out a dividend cash is moved from one party to another).

21.1.7.4 Summary

You have learned how to use lifecycle rules and events to describe the behavior of an instrument. The key concepts to take away are:

- Lifecycle events represent different ways of how an instrument can evolve.

- A lifecycle rule contains logic to calculate the effects an event has on an instrument and its holdings.

- A claim rule is used to instruct settlement for a given effect using a holding.

21.2 Settlement

This section explains how the settlement processes of Daml Finance work in detail. It combines a step by step description of different workflows with supporting code.

The following tutorials are available:

- The [Enhanced Transfers](#) tutorial builds upon the basic [Transfer](#) tutorial from the Getting Started section. Specifically, we explore how to configure the controllers that need to authorize incoming transfers (credits) and outgoing transfers (debits) to and from an account, respectively.

- The [Internal Settlement](#) tutorial, an extension of the basic [Settlement](#) Getting Started tutorial, illustrates how holdings can be transferred within a single custodian through a settlement workflow involving batches and related instructions. The allocation process of such instructions involves methods for committing a pre-existing holding (`Pledge`), a newly created holding (`CreditReceiver`), and a holding received simultaneously (`PassThroughFrom`). The approval methods include taking delivery of a holding to an account (`TakeDelivery`), immediately nullifying the holding (`DebitSender`), and passing the holding through (as allocation) to another instruction (`PassThroughTo`).

- The [Intermediated Settlement](#) tutorial builds upon the [Internal Settlement](#) tutorial and shows how to make use of a `RouteProvider` to settle instructions across account hierarchies involving more than one custodian.

21.2.1 Download the Code for the Tutorials

As a prerequisite, make sure that the [Daml SDK](#) is installed on your machine.

Open a terminal and run:

```
daml new finance-settlement --template=finance-settlement
```

This creates a new folder with contents from our template. Navigate to the `finance-settlement` folder and then run the following to download the required Daml Finance packages:

```
./get-dependencies.sh
```

or, if you are using Windows

```
./get-dependencies.bat
```

Finally, you can start Daml Studio to inspect the code and run the project's scripts:

```
daml studio
```

21.2.2 Enhanced Transfers

In this tutorial, we delve deeper into the concepts that were introduced in our getting-started tutorials. In particular, we will extend on the [transfer](#) tutorial.

We begin by understanding the simple form of settlement. It transpires when a customer's funds are transferred to another account within the same bank. Consequently, the sender's account is debited (balance decreases), and the recipient's account is credited (balance increases). This process is internally managed within the bank's systems and usually occurs instantly, as it doesn't require interaction with external systems or institutions.

In Daml Finance, such fund transfers are not necessarily represented by a settlement workflow that involves allocating and approving instructions. Instead, a direct transfer of funds can occur between two parties, such as Alice and Bob. This transfer debits the sending account and atomically credits the receiving account.

Next, we will explore how to configure the controllers responsible for authorizing incoming transfers (credits) and outgoing transfers (debits) of holdings to an account.

21.2.2.1 Configuring Account Controllers

The [Controllers](#) data type specifies the parties that need to authorize incoming and outgoing transfers to an account.

For this tutorial, we provide four example scripts illustrating various incoming and outgoing controller settings:

Script	Incoming Controllers	Outgoing Controllers
runDualControlTransfer	Anyone	Both (owner and custodian)
runDiscretionaryTransfer	Custodian	Custodian
runSovereignTransfer	Owner	Owner
runUnilateralTransfer	Anyone	Owner

Each script begins by running a setup script `runSetupTransferRequestWith` that requests a transfer of a holding from Alice to Bob at the Bank. The setup script takes a configuration as input to set up Alice's and Bob's account controllers, as outlined in the table above.

The last step of the setup script creates a transfer request of a holding from Alice to Bob:

```

let
  transferRequest = Transfer.Request with
    instructor -- This is equivalent to writing instructor = instructor
    receiverAccount = bobAccount
    transferableCid = aliceHoldingCid
    accepted = mempty
    observers = fromList [alice, bob, bank]
  transferRequestCid <- submit instructor do createCmd transferRequest

```

The transfer Request template is designed for the stepwise collection of the necessary authorizations for transferring a holding to a new owner:

```

template Request
  with
    instructor : Party
      -- ^ The party who creates the transfer request, but doesn't necessarily
      -- have to authorize it.
    receiverAccount : AccountKey
      -- ^ The account to which the holding is sent.
    transferableCid : ContractId Transferable.I
      -- ^ The holding instance to be sent.
    accepted : Set Party
      -- ^ Current set of parties that accept the transfer.
    observers : Set Party
      -- ^ Observers.
  where
    signatory instructor, accepted
    observer observers

    choice Accept : ContractId Request
      with
        actors : Set Party
        controller actors
      do
        create this with accepted = actors <> this.accepted

    choice Effectuate : ContractId Transferable.I
      with
        actors : Set Party
        controller actors
      do
        exercise transferableCid Transferable.Transfer with
          actors = actors <> this.accepted
          newOwnerAccount = receiverAccount

```

Dual Control

In the runDualControlTransfer script, both the custodian and the owner of an account must authorize outgoing transfers (debits), while incoming transfers (credits) require no authorization.

This script begins by setting up accounts accordingly and creating a transfer request instance:

```

let
  dualControl = AccountControllers with

```

(continues on next page)

(continued from previous page)

```

    incoming = Anyone
    outgoing = Both
SetupTransferRequest{bank; alice; bob; instructor; transferRequestId} <-
    runSetupTransferRequestWith dualControl

```

To execute the transfer, both the Bank and Alice must authorize:

```

transferRequestId <- submit bank do
    exerciseCmd transferRequestId Transfer.Accept with actors = singleton bank
submit alice do
    exerciseCmd transferRequestId Transfer.Effectuate with actors = singleton
↪alice

```

Discretionary

The `runDiscretionaryTransfer` script specifies that the custodian controls both incoming and outgoing transfers:

```

let
    discretionary = AccountControllers with
        incoming = Custodian
        outgoing = Custodian
    setupState@SetupTransferRequest{bank; alice; bob; instructor;
↪transferRequestId} <-
        runSetupTransferRequestWith discretionary

```

Following the setup, the Bank can execute the transfer single-handedly:

```

submit bank do
    exerciseCmd transferRequestId Transfer.Effectuate with actors = singleton
↪bank

```

Sovereign

In the `runSovereignTransfer` script, the owner controls both incoming and outgoing transfers:

```

let
    sovereign = AccountControllers with
        incoming = Owner
        outgoing = Owner
    SetupTransferRequest{bank; alice; bob; instructor; transferRequestId} <-
        runSetupTransferRequestWith sovereign

```

As Alice is the outgoing controller of the sending account, and Bob is the incoming controller of the receiving account, both need to authorize the transfer:

```

transferRequestId <- submit bob do
    exerciseCmd transferRequestId Transfer.Accept with actors = singleton bob
submit alice do
    exerciseCmd transferRequestId Transfer.Effectuate with actors = singleton
↪alice

```

Unilateral

In our final example script, *runUnilateralTransfer*, the owner controls outgoing transfers, while incoming transfers require no additional authorization:

```
let
  unilateral = AccountControllers with
    incoming = Anyone
    outgoing = Owner
SetupTransferRequest(bank; alice; bob; instructor; transferRequestId) <-
  runSetupTransferRequestWith unilateral
```

Once the setup is complete, Alice can independently execute the transfer to Bob:

```
transferRequestId <- submit alice do
  exerciseCmd transferRequestId Transfer.Effectuate with actors = singleton
  ↪alice
```

21.2.2.2 Summary

By now, you should understand how to configure incoming and outgoing controllers for accounts based on your requirements. Key concepts to remember include:

- To execute a transfer between a sender and a receiver, the outgoing controllers of the sending account and the incoming controllers of the receiving account need to authorize it.

- The required authorization can be provided by a generalized propose-accept template, which allows more than one party to accept.

Ownership transfers usually occur as part of a larger financial transaction. The next tutorials will guide you on how to create such a transaction and how to settle it atomically.

21.2.3 Internal Settlement

This tutorial builds upon the concepts introduced in the [Settlement](#) getting-started tutorial. Compared to our previous [Enhanced Transfers](#) tutorial, which demonstrated the direct transfer of a holding from sender to receiver (at a single custodian), it delves further into the settlement mechanism with a batch and related instructions. This process enables the adjustment of record books across multiple entities and instrument holdings simultaneously.

In this tutorial, we will limit the complexity by focusing on a single custodian and the transfer of a single instrument. The next tutorial will explore the broader scenario involving multiple custodians. Eager learners are encouraged to extend this tutorial and the following one by incorporating more than one instrument as an exercise.

21.2.3.1 Understanding Internal Settlement with Examples

To start, let us briefly revisit the settlement process which was explained in the [Settlement](#) section. A [Batch](#) consists of one or more [Instructions](#). Each instruction signifies a [RoutedStep](#), delineating the quantity of an instrument to be transferred from a sender to a receiver at a specific custodian. For an instruction to be prepared for settlement (or execution), the sender-side must furnish an [Allocation](#), and the receiver-side must provide an [Approval](#).

This tutorial will walk you through three example scripts for settling instructions at a single custodian: `runWrappedTransferSettlement`, `runCreditDebitSettlement`, and `runPassThroughSettlement`.

The allocation processes in these scripts involve methods to commit a pre-existing holding (`Pledge`), a newly created holding (`CreditReceiver`), and a holding received concurrently (`PassThroughFrom`).

The approval methods entail taking delivery of a holding to an account (`TakeDelivery`), immediately nullifying the holding (`DebitSender`), and passing the holding through (as allocation) to another instruction (`PassThroughTo`).

Each script kicks off with `runSetupInternalSettlement` which initiates parties, a cash instrument issued by the Central Bank, accounts for Alice, Bob, and Charlie at a Bank, and a settlement factory:

```
SetupInternalSettlement
{ instrument
; bank
; alice
; aliceAccount
; aliceHoldingCid
; bob
; bobAccount
; charlie
; charlieAccount
; instructor
; settlementFactoryCid
} <- runSetupInternalSettlement
```

The settlement factory is employed by a party, known as the *instructor*, to create a batch and instructions from a list of routed steps. In the scripts, the instructor is also responsible for settling the batch once all instructions have been allocated and approved.

Wrapped Transfer

The first example encapsulates a transfer from Alice to Bob, from our previous [Enhanced Transfers](#) tutorial, by creating a batch and a single instruction:

```
let
  routedStep = RoutedStep with
    custodian = bank
    sender = alice
    receiver = bob
    quantity = qty 1000.0 instrument
```

(continues on next page)

(continued from previous page)

```

-- Generate settlement instructions from a list of `RoutedStep`s.
(batchCid, [instructionCid]) <-
  submit instructor do
    exerciseCmd settlementFactoryCid SettlementFactory.Instruct with
      instructor -- This is equivalent to writing instructor = instructor
      consenters = mempty
      settlers = singleton instructor
      id = Id "1"
      description = "Transfer from Alice to Bob"
      contextId = None
      routedSteps = [routedStep]
      settlementTime = None -- i.e., immediate settlement

```

Here, Alice allocates by pledging a holding, Bob approves by taking delivery to his account at the Bank, and the instructor finally settles the batch:

```

-- i. Alice allocates.
(instructionCid, _) <- submit alice do
  exerciseCmd instructionCid Instruction.Allocate with
    actors = singleton alice
    allocation = Pledge $ toInterfaceContractId aliceHoldingCid

-- ii. Bob approves.
instructionCid <- submit bob do
  exerciseCmd instructionCid Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount

-- iii. Instructor executes the settlement.
[bobHoldingCid] <- submit instructor do
  exerciseCmd batchCid Batch.Settle with
    actors = singleton instructor

```

Note that this occurs without involving the Bank, and either Alice or Bob could also take the role as the instructor. As a result of running this script, Alice's holding is transferred to Bob.

Credit and Debit

An alternative approach to transfer the holding from Alice to Bob includes the Bank as an intermediary.

```

let
  routedStep1 = RoutedStep with
    custodian = bank
    sender = alice
    receiver = bank
    quantity = qty 1000.0 instrument
  routedStep2 = routedStep1 with
    sender = bank
    receiver = bob

-- Generate settlement instructions from a list of `RoutedStep`s.
(batchCid, [instructionCid1, instructionCid2]) <-

```

(continues on next page)

(continued from previous page)

```

submit instructor do
  exerciseCmd settlementFactoryCid SettlementFactory.Instruct with
    instructor
    consenters = mempty
    settlers = singleton instructor
    id = Id "1"
    description = "Movement of holding from Alice to Bob through debit and
↳credit"
    contextId = None
    routedSteps = [routedStep1, routedStep2]
    settlementTime = None -- i.e., immediate settlement

```

Similar to the previous scenario, Alice allocates by pledging a holding, and Bob approves by taking delivery to his account. However, in this case, the Bank plays an intermediary role by allocating and approving, debiting the sender and crediting the receiver, respectively:

```

-- i. Alice allocates.
(instructionCid1, _) <- submit alice do
  exerciseCmd instructionCid1 Instruction.Allocate with
    actors = singleton alice
    allocation = Pledge $ toInterfaceContractId aliceHoldingCid

-- ii. Bob approves.
instructionCid2 <- submit bob do
  exerciseCmd instructionCid2 Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount

-- iii. Bank approves and allocates.
instructionCid1 <- submit bank do
  exerciseCmd instructionCid1 Instruction.Approve with
    actors = singleton bank
    approval = DebitSender
(instructionCid2, _) <- submit bank do
  exerciseCmd instructionCid2 Instruction.Allocate with
    actors = singleton bank
    allocation = CreditReceiver

-- iv. Instructor executes the settlement.
[bobHoldingCid] <- submit instructor do
  exerciseCmd batchCid Batch.Settle with
    actors = singleton instructor

```

We could have made the Bank approve and allocate its instructions by taking delivery to an account it owns and pledging a holding where it acts as the custodian. However, this would require the creation of dummy accounts and holdings, which can be avoided using the `DebitSender` and `CreditReceiver` methods. These methods can only be used when the receiver (resp. the sender) corresponds to the custodian.

Pass Through

The final script of this tutorial demonstrates how holdings received as part of the same settlement process can be allocated to a subsequent instruction. We again use two instructions, `instruction1` and `instruction2`, but now with Charlie as the intermediary:

```
let
  routedStep1 = RoutedStep with
    custodian = bank
    sender = alice
    receiver = charlie
    quantity = qty 1000.0 instrument
  routedStep2 = routedStep1 with
    sender = charlie
    receiver = bob

-- Generate settlement instructions from a list of `RoutedStep`s.
(batchCid, [instructionCid1, instructionCid2]) <-
  submit instructor do
    exerciseCmd settlementFactoryCid SettlementFactory.Instruct with
      instructor
      consenters = mempty
      settlers = singleton instructor
      id = Id "1"
      description = "Transfer from Alice to Bob via Charlie"
      contextId = None
      routedSteps = [routedStep1, routedStep2]
      settlementTime = None -- i.e., immediate settlement
```

Like in the previous examples, Alice allocates by pledging a holding, and Bob approves by taking delivery to his account. The intermediary, Charlie, allocates using `PassThroughTo` (`charlieAccount`, `instruction2`) and approves with `PassThroughFrom` (`charlieAccount`, `instruction1`), essentially enabling the holding Charlie receives from Alice to pass-through to Bob:

```
-- i. Alice allocates.
(instructionCid1, _) <- submit alice do
  exerciseCmd instructionCid1 Instruction.Allocate with
    actors = singleton alice
    allocation = Pledge $ toInterfaceContractId aliceHoldingCid

-- ii. Bob approves.
instructionCid2 <- submit bob do
  exerciseCmd instructionCid2 Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount

-- iii. Charlie approves and allocates (with pass-through).
instructionKey2 <- retrieveKey charlie instructionCid2
instructionCid1 <- submit charlie do
  exerciseCmd instructionCid1 Instruction.Approve with
    actors = singleton charlie
    approval = PassThroughTo (charlieAccount, instructionKey2)
instructionKey1 <- retrieveKey charlie instructionCid1
instructionCid2 <- submit charlie do
  exerciseCmd instructionCid2 Instruction.Allocate with
```

(continues on next page)

(continued from previous page)

```

actors = singleton charlie
allocation = PassThroughFrom (charlieAccount, instructionKey1)

-- iv. Instructor executes the settlement.
[bobHoldingCid] <- submit instructor do
  exerciseCmd batchCid Batch.Settle with
    actors = singleton instructor

```

The significant advantage of the pass-through method is that Charlie doesn't need any holdings upfront as he's at a net zero position for incoming and outgoing holdings in this settlement process.

Note that the Bank could have utilized the pass-through approach to achieve the same result in the previous script, but it would still require a `dummy` account.

21.2.3.2 Summary

By the end of this tutorial, you should have a good grasp on how to apply various allocation and approval methods to instructions. The key points are:

- A custodian can utilize the `DebitSender` and `CreditReceiver` methods to bypass the need for `dummy` accounts and holdings when approving and allocating instructions, respectively.
- A holding settled via an intermediary at the same custodian can be passed through, thus eliminating the requirement for the intermediary to possess the holding upfront.

In the forthcoming tutorial, we will delve into more complex settlement transactions involving a transfer across multiple custodians.

21.2.4 Intermediated Settlement

This tutorial expands upon the principles discussed in our previous [Internal Settlement](#) tutorial, providing an in-depth exploration of intermediated settlement involving a multi-level account hierarchy across different custodians.

21.2.4.1 Understanding Intermediated Settlement with Examples

This tutorial features two example scripts, `runWrappedTransfersSettlement` and `runRouteProviderSettlement`, illustrating how to settle a batch with multiple instructions and custodians.

Each script commences with `runSetupIntermediatedSettlement`, initiating parties, establishing an instrument issued by the Central Bank, and setting up an account hierarchy rooted at the Central Bank. This hierarchy includes two custodian banks, Bank1 and Bank2, and their respective clients Alice, Bob, and Charlie. Holdings are created for `Alice@Bank1`, `Bank1@CentralBank`, and `Charlie@Bank2`:

```

SetupIntermediatedSettlement
{ instrument
; bank1; bank2
; alice; aliceAccount1; aliceHoldingCid
; bob; bobAccount2
; charlie; charlieAccount1; charlieAccount2; charlieHoldingCid

```

(continues on next page)

(continued from previous page)

```

; instructor
; settlementFactoryCid
} <- runSetupIntermediatedSettlement

```

The below diagram illustrates the setup, where edges represent accounts and stars (*) denote holdings:

Wrapped Transfers: A Detailed Analysis

Our first example elucidates how two transfers at separate custodians can be consolidated into a single batch. The routed steps are as follows:

```

let
  routedStep1 = RoutedStep with
    custodian = bank1
    sender = alice
    receiver = charlie
    quantity = qty 1000.0 instrument
  routedStep2 = routedStep1 with
    custodian = bank2
    sender = charlie
    receiver = bob

```

These steps are converted into a batch and instructions:

```

(batchCid, [instructionCid1, instructionCid2]) <-
  submit instructor do
    exerciseCmd settlementFactoryCid SettlementFactory.Instruct with
      instructor
      consenters = mempty
      settlers = singleton instructor
      id = Id "1"
      description = "Transfer from Alice to Bob via Charlie"
      contextId = None
      routedSteps = [routedStep1, routedStep2]
      settlementTime = None -- i.e., immediate settlement

```

The following diagram visualizes this pre- and post-settlement of the batch, where > signifies settlement instructions, and stars (*) represents the holdings:

Similar to the Internal Settlement tutorial, Alice allocates her Bank1 holding through a pledge, while Bob approves its instruction by taking delivery at his account at Bank2. The intermediary, Charlie, approves by taking delivery to his Bank1 account and allocates by pledging his pre-existing holding at Bank2:

```
-- i. Alice allocates.
(instructionCid1, _) <- submit alice do
  exerciseCmd instructionCid1 Instruction.Allocate with
    actors = singleton alice
    allocation = Pledge $ toInterfaceContractId aliceHoldingCid

-- ii. Bob approves.
instructionCid2 <- submit bob do
  exerciseCmd instructionCid2 Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount2

-- iii. Charlie approves and allocates (with pass-through).
instructionCid1 <- submit charlie do
  exerciseCmd instructionCid1 Instruction.Approve with
    actors = singleton charlie
    approval = TakeDelivery charlieAccount1
instructionCid2 <- submit charlie do
  exerciseCmd instructionCid2 Instruction.Allocate with
    actors = singleton charlie
    allocation = Pledge $ toInterfaceContractId charlieHoldingCid

-- iii. Instructor executes the settlement.
[charlieHoldingCid, bobHoldingCid] <- submit instructor do
  exerciseCmd batchCid Batch.Settle with
    actors = singleton instructor
```

Important to note, Charlie cannot pass-through Alice's holding to Bob, as in the [Internal Settlement](#) tutorial, due to the holdings having different custodians. Therefore, for settlement to occur, Charlie needs a holding at Bank2. The settlement alters Charlie's counterparty risk, shifting it from Bank1 to Bank2. This is a situation Charlie might wish to avoid. The upcoming example shows how to involve a route provider, eliminating the need for Charlie to hold any upfront holdings, thus preserving his counterparty exposure.

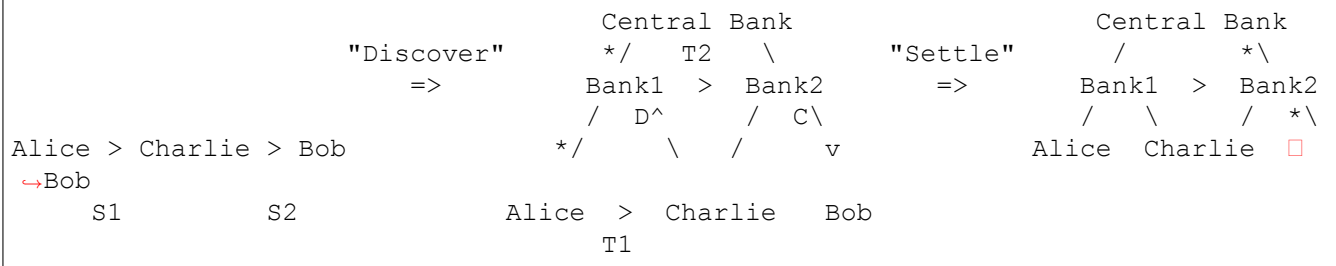

Route Provider: An Alternative Approach

Our second example follows a similar setup to the first, involving a settlement step between Alice and Charlie (S1), and another between Charlie and Bob (S2). However, these steps do not specify a custodian, unlike the routed steps.

To convert the settlement steps S1 and S2 into routed steps, we engage a route provider. The provider suggests preferable routes to the Central Bank for each client. During the `Discover` action, each step is transformed into a sequence of routed steps

```
S1 -> (T1)
S2 -> (D, T2, C)
```

where T1 and T2 denote settlements by transfers, D represents a Debit, and C signifies a Credit. The diagram below depicts the effects of the discovery and settlement process:

Let's begin with the `Discover` action:

```
let
  quantity = qty 1000.0 instrument
  -- Alice to Charlie step.
  step1 = Step with sender = alice; receiver = charlie; quantity
  -- Charlie to Bob step.
  step2 = Step with sender = charlie; receiver = bob; quantity

  -- Using a route provider to discover settlement route, with intermediaries,
  ↪ from Alice to Bob for
  -- the instrument.
  let
    paths = Map.fromList
      [ ( show instrument.id
        , Hierarchy with
          rootCustodian = cb
          pathsToRootCustodian = [[alice, bank1], [charlie, bank1], [bob,
↪ bank2]]
        )
      ]
    routeProviderCid <- toInterfaceContractId @RouteProvider.I <$> submit
    ↪ instructor do
      createCmd IntermediatedStatic with provider = instructor; paths; observers =
↪ mempty
    routedSteps <- submit instructor do
      exerciseCmd routeProviderCid RouteProvider.Discover with
        discoverors = singleton instructor; contextId = None; steps = [step1, step2]
      -- Sanity check.
  let
    routedStep1 = RoutedStep with custodian = bank1; sender = alice; receiver =
↪ charlie; quantity
    routedStep2 = RoutedStep with custodian = bank1; sender = charlie; receiver =
↪ bank1; quantity
    routedStep3 = RoutedStep with custodian = cb; sender = bank1; receiver =
↪ bank2; quantity
    routedStep4 = RoutedStep with custodian = bank2; sender = bank2; receiver =
↪ bob; quantity
    routedSteps === [routedStep1, routedStep2, routedStep3, routedStep4]
```

Followed by the creation of the batch and instructions:

```
(batchCid, [instructionCid1, instructionCid2, instructionCid3,
↪ instructionCid4]) <-
  submit instructor do
    exerciseCmd settlementFactoryCid SettlementFactory.Instruct with
      instructor
```

(continues on next page)

(continued from previous page)

```

consenters = mempty
settlers = singleton instructor
id = Id "1"
description = "Transfer from Alice to Bob via intermediaries"
contextId = None
routedSteps
settlementTime = None -- i.e., immediate settlement

```

Finally, Alice, Charlie, Bank1, Bank2, and Bob allocate and approve their instructions accordingly:

```

-- i. Alice allocates
(instructionCid1, _) <- submit alice do
  exerciseCmd instructionCid1 Instruction.Allocate with
    actors = singleton alice
    allocation = Pledge $ toInterfaceContractId aliceHoldingCid

-- ii. Bob approves.
instructionCid4 <- submit bob do
  exerciseCmd instructionCid4 Instruction.Approve with
    actors = singleton bob
    approval = TakeDelivery bobAccount2

-- iii. Charlie approves and allocates.
instruction2 <- retrieveKey charlie instructionCid2
instructionCid1 <- submit charlie do
  exerciseCmd instructionCid1 Instruction.Approve with
    actors = singleton charlie
    approval = PassThroughTo (charlieAccount1, instruction2)
instruction1 <- retrieveKey charlie instructionCid1
(instructionCid2, _) <- submit charlie do
  exerciseCmd instructionCid2 Instruction.Allocate with
    actors = singleton charlie
    allocation = PassThroughFrom (charlieAccount1, instruction1)

-- iv. Bank1 approves and allocates.
instructionCid2 <- submit bank1 do
  exerciseCmd instructionCid2 Instruction.Approve with
    actors = singleton bank1
    approval = DebitSender
(instructionCid3, _) <- submit bank1 do
  exerciseCmd instructionCid3 Instruction.Allocate with
    actors = singleton bank1
    allocation = Pledge $ toInterfaceContractId bank1HoldingCid

-- v. Bank2 approves and allocates.
instructionCid3 <- submit bank2 do
  exerciseCmd instructionCid3 Instruction.Approve with
    actors = singleton bank2
    approval = TakeDelivery bank2Account
(instructionCid4, _) <- submit bank2 do
  exerciseCmd instructionCid4 Instruction.Allocate with
    actors = singleton bank2
    allocation = CreditReceiver

-- vi. Instructor executes the settlement.
[charlierHoldingCid, bobHoldingCid] <- submit instructor do

```

(continues on next page)

(continued from previous page)

```
exerciseCmd batchCid Batch.Settle with  
  actors = singleton instructor
```

Once the batch is settled, all instructions are executed atomically, causing a coordinated change in the account hierarchy's holdings. Importantly, Charlie acted as an intermediary, providing a route from Alice to Bob, without having to use any holdings upfront.

21.2.4.2 Summary

You know how to define complex transactions and settle them atomically. Crucial points to remember are:

- A route provider serves the purpose of discovering settlement routes or routed steps for each settlement step.

- Viewing the account hierarchy as a tree – with the Central Bank at the root, custodians on the second level, and clients as leaves – transfers occur on horizontally directed routed steps, debits on upwards directed routed steps, and credits on downward directed routed steps.

As a challenge for the curious reader, try extending these examples to settle two instruments using settlement routes across two different account hierarchies.

21.3 Lifecycling

This section explains how to lifecycle instruments in Daml Finance. Each tutorial combines a step by step description of different workflows with supporting code.

The following tutorials are available:

- The [Time-based lifecycling](#) tutorial uses a fixed rate bond as an example to demonstrate time-based lifecycling.

- The [Observations](#) tutorial uses a floating rate bond as a sample instrument to show how Observations work. This applies to instruments whose payoff depends on an underlying asset.
- The [Election-based lifecycling](#) tutorial uses a callable bond to explain how to create and process elections. This applies to instruments that require an active choice by one of the stakeholders.

Each tutorial builds on top of the previous ones, so they should ideally be followed in order.

21.3.1 Download the Code for the Tutorials

As a prerequisite, make sure that the [Daml SDK](#) is installed on your machine.

Open a terminal and run:

```
daml new finance-lifecycling --template=finance-lifecycling
```

This creates a new folder with contents from our template. Navigate to the `finance-lifecycling` folder and then run the following to download the required Daml Finance packages:

```
./get-dependencies.sh
```

or, if you are using Windows

```
./get-dependencies.bat
```

Finally, you can start Daml Studio to inspect the code and run the project's scripts:

```
daml studio
```

21.3.2 Time-based lifecycling (using a fixed rate bond)

This tutorial describes how to lifecycle instruments with pre-defined payments, e.g. a fixed rate bond. It is similar to the [Lifecycling tutorial](#), in that it describes how lifecycle rules and events can be used to evolve instruments over time. However, there is one main difference:

The [Lifecycling tutorial](#) describes a dividend event, which is something that the issuer defines on an *ongoing* basis. Only once the date and amount of a dividend payment has been defined, the issuer creates a distribution event accordingly.

This tutorial describes a fixed rate bond, where all coupon payments are defined *in advance*. They are all encoded in the instrument definition. Hence, the issuer does not need to create distribution events on an ongoing bases. Instead, one lifecycle rule in combination with time events (a date clock) are used to lifecycle the bond.

Check out the [Lifecycling concepts](#) for a more in-depth description of the evolution of financial instruments over their lifetime.

In this tutorial, we are going to:

1. create a fixed rate bond instrument and book a holding on it
2. create a lifecycle rule
3. create a lifecycle event (time event: `DateClockUpdate`)
4. process the event to produce the effects of a coupon payment
5. instruct settlement by presenting a bond holding
6. settle the resulting batch atomically

This example builds on the previous [Settlement](#) tutorial script. Some required concepts are explained there, so please check out that tutorial before you continue below.

21.3.2.1 Run the Script

The code for this tutorial can be executed via the `runFixedRateBond` script in the `FixedRateBond.daml` module.

Instrument and Holding

For the purpose of showcasing time-based lifecycling, we need a suitable sample instrument. [Fixed rate bonds](#) pay a constant coupon rate at the end of each coupon period. The [Bond Instrument packages](#) page describes this instrument in more detail. Here, we briefly show how to create the bond instrument using a factory:

```
-- Create a fixed rate bond factory
fixedRateBondFactoryCid <- toInterfaceContractId @FixedRateBondFactory.I <$>□
→ submit bank do
    createCmd FixedRateBond.Factory with
```

(continues on next page)

(continued from previous page)

```

    provider = bank
    observers = mempty

-- Define an instrument key for the bond
let
    bondInstrument = InstrumentKey with
        issuer = bank
        depository = bank
        id = Id "FixedRateBond"
        version = "0"
        holdingStandard = TransferableFungible
    initialTimestamp = dateToDateClockTime issueDate

-- Bank creates the bond instrument
fixedRateBondCid <- submit bank do
    exerciseCmd fixedRateBondFactoryCid FixedRateBondFactory.Create with
        fixedRate = FixedRate with
            instrument = bondInstrument
            description = "Instrument representing units of a fixed rate bond"
            couponRate
            periodicSchedule
            holidayCalendarIds
            calendarDataProvider = bank
            dayCountConvention
            currency = usdInstrument
            notional
            lastEventTimestamp = initialTimestamp
        observers = Map.fromList pp

```

We also create a bond holding in Bob's account:

```

-- Credit Bob's account with a bond holding
bobRequestCid <- submit bob do
    createCmd CreditAccount.Request with
        account = bobAccount
        instrument = bondInstrument
        amount = 100000.0
    bobBondHoldingCid <- submit bank do exerciseCmd bobRequestCid CreditAccount.
    ↪Accept

```

A holding represents the ownership of a certain amount of an *instrument* by an owner at a custodian. Check out the [Holdings](#) tutorial for more details.

Now, we have both an instrument definition and a holding. Let us proceed to lifecycle the bond, which is the main purpose of this tutorial.

Lifecycle Events and Rule

As mentioned earlier, we only need one single lifecycle rule to process all time events (since all coupon payments are pre-defined in the instrument terms):

```
-- Create a lifecycle rule
lifecycleRuleCid <- toInterfaceContractId @Lifecycle.I <$> submit bank do
  createCmd Rule with
    providers = Set.singleton bank
    observers = mempty
    lifecycler = bank
    id = Id "LifecycleRule"
    description = "Rule to lifecycle an instrument"
```

In order to lifecycle a coupon payment, we create a time event corresponding to the date of the first coupon:

```
-- Create a clock update event
firstCouponClockEventCid <- createClockUpdateEvent bank firstCouponDate mempty
```

Note that it is the bank that actively creates a [DateClockUpdateEvent](#). This results in more control when to actually process the coupon payment. One could also use [LedgerTime](#), but that could cause problems in some scenarios, for example:

The system is down when the coupon should be processed. Processing it the next day is difficult if ledger time is automatically used, because the date returned from the ledger no longer matches the intended lifecycling date.

A global ledger containing trades from regions in different time zones may require flexibility regarding when, in relation to ledger time, to process coupons and other events.

The coupon payment depends on market data, which the data provider occasionally provides with a delay. Retroactively processing this is simpler if the lifecycler can provide the today date.

Now, we have what we need to actually lifecycle the bond. The `Evolve` choice of the lifecycle rule is exercised to process the time event:

```
-- Try to lifecycle the instrument
(lifecycleCid, [effectCid]) <- submit bank do
  exerciseCmd lifecycleRuleCid Lifecycle.Evolve with
    eventCid = firstCouponClockEventCid
    observableCids = []
    instrument = bondInstrument
```

Both the [LedgerTime](#) and the [DateClock](#) implement the [TimeObservable](#) interface, which is used by `Evolve` to specify the current time for the lifecycling.

The result of this is an effect describing the per-unit asset movements to be executed for bond holders. Each holder can now present their holding to *claim* the effect and instruct settlement of the associated entitlements.

A [Claim Rule](#) allows a holder of the target instrument to claim the effect resulting from the time event:

```
-- Create the claim rule
lifecycleClaimRuleCid <- toInterfaceContractId @Claim.I <$> submit bank do
  createCmd Claim.Rule with
    provider = bank
```

(continues on next page)

(continued from previous page)

```

claimers = Set.singleton bob
settlers = Set.singleton bob
routeProviderCid
settlementFactoryCid
netInstructions = False

```

By presenting their holding they can instruct the settlement of the holding transfers described in the effect:

```

result <- submitMulti [bob] [public] do
  exerciseCmd lifecycleClaimRuleCid Claim.ClaimEffect with
    claimer = bob
    holdingCids = [bobBondHoldingCid]
    effectCid -- This is equivalent to writing effectCid = effectCid
    batchId = Id "BondSettlement"
  let [bobInstructionCid, bankInstructionCid, couponInstructionCid] = result.
  ↳ instructionCids

```

As a side-effect of settling the entitlements, the presented holding is exchanged for a holding of a new bond version. This is to prevent a holder from benefiting from a given effect twice (in our case: receiving the same coupon twice).

In our example of a bond coupon, only a single instruction is generated: the movement of cash from the bank to the bond holder. This instruction along with its batch is settled the usual way, as described in the previous [Settlement](#) tutorial.

```

-- Allocate instruction
(bobInstructionCid, _) <- submit bob do
  exerciseCmd bobInstructionCid Instruction.Allocate with
    actors = Set.singleton bob
    allocation = Pledge bobBondHoldingCid

(bankInstructionCid, _) <- submit bank do
  exerciseCmd bankInstructionCid Instruction.Allocate with
    actors = Set.singleton bank
    allocation = CreditReceiver

(couponInstructionCid, _) <- submit bank do
  exerciseCmd couponInstructionCid Instruction.Allocate with
    actors = Set.singleton bank
    allocation = CreditReceiver

-- Approve instruction
bobInstructionCid <- submit bank do
  exerciseCmd bobInstructionCid Instruction.Approve with
    actors = Set.singleton bank
    approval = DebitSender

bankInstructionCid <- submit bob do
  exerciseCmd bankInstructionCid Instruction.Approve with
    actors = Set.singleton bob
    approval = TakeDelivery bobAccount

couponInstructionCid <- submit bob do
  exerciseCmd couponInstructionCid Instruction.Approve with

```

(continues on next page)

(continued from previous page)

```

actors = Set.singleton bob
approval = TakeDelivery bobAccount

-- Settle batch
submitMulti [bob] [public] do
  exerciseCmd result.batchCid Batch.Settle with actors = Set.singleton bob

```

Note that the bank in this case does not actually transfer the cash from another account, but simply credits Bob's account by using the `CreditReceiver` allocation type. In a real-world bond coupon scenario one would additionally model the flow of funds from the issuer to the bank using the same lifecycle process as described above.

Check out the [Settlement concepts](#) for a more in-depth description of the different steps in the settlement process and the settlement modes supported by the library.

Note that the lifecycling process above is not limited to fixed coupon bonds. It also works for other instruments with pre-defined payments, for example:

Instrument	Pre-defined variable
Foreign exchange swaps	FX rate
Currency swaps	Interest rates (on both legs)

21.3.2.2 Frequently Asked Questions

Which party should create and sign the lifecycle rules and events?

In the simplified scenario for this tutorial, we have used the bank as both the *issuer* and *depository* for the instruments involved. In a real-world case, instruments and their corresponding lifecycle rules and events would be maintained by an actual issuer, with the depository acting as a 3rd-party trust anchor.

Which parties typically take which actions in the lifecycle workflow?

The lifecycle interfaces governing the process leave the controllers of the various choices in the process up to the implementation.

Typically, we would expect the issuer of an instrument to define the instrument terms, which in our example above govern the date and amount of each bond coupon.

Lifecycle rules on the other hand are often controlled by 3rd-party calculation agents.

The claiming of lifecycle effects is by default the responsibility of the owner of a holding. If instead the owner wants to delegate this responsibility to their custodian they can do so via a delegation contract.

The party executing settlement can be chosen as well, as described in the previous tutorial on [Settlement](#).

21.3.2.3 Summary

You have learned how to create a fixed coupon bond and how to use a lifecycle rule and events to process the payments pre-defined by the instrument. The key concepts to take away are:

Lifecycle events cause the bond instrument to evolve over time.

A lifecycle rule contains logic to calculate the effects an event has on an instrument and its holdings.

A claim rule is used to instruct settlement for a given effect using a holding.

21.3.3 Observations (using a floating rate bond)

This tutorial describes how to define observations. It builds on the previous [Time-based Lifecycling](#) tutorial, which uses a fixed rate bond where all coupons are pre-defined using a constant annualized rate. In contrast, the coupons of a floating rate bond depend on the value of a reference rate for each coupon period. Hence, the lifecycling framework requires the future values of the reference rate. This is referred to as *Observations*, which is the main topic of this tutorial.

In this tutorial, we are going to:

1. create a floating rate bond instrument and book a holding on it
2. create an observation of the floating rate, which is used to define the coupon payment
3. reuse the lifecycle rule and lifecycle event from the fixed rate bond tutorial
4. process the event to produce the effects of a coupon payment
5. instruct settlement by presenting a bond holding
6. settle the resulting batch atomically

21.3.3.1 Run the Script

The code for this tutorial can be executed via the `runFloatingRateBond` script in the `FloatingRateBond.daml` module.

Instrument and Holding

For the purpose of showcasing the [Observation](#) concept, we need a suitable sample instrument. [Floating rate bonds](#) pay a coupon which is determined by a reference rate, e.g. 3M Libor. The [Bond Instrument packages](#) page describes this instrument in more detail. Here, we briefly show how to create the bond instrument using a factory:

```
-- Create a floating rate bond factory
floatingRateBondFactoryCid <- toInterfaceContractId @FloatingRateBondFactory.I <
↪$> submit bank do
  createCmd FloatingRateBond.Factory with
    provider = bank
    observers = mempty

-- Define an instrument key for the bond
let
  bondInstrument = InstrumentKey with
    issuer = bank
    depository = bank
```

(continues on next page)

(continued from previous page)

```

id = Id "FloatingRateBond"
version = "0"
holdingStandard = TransferableFungible

-- Bank creates the bond instrument
floatingRateBondCid <- submit bank do
  exerciseCmd floatingRateBondFactoryCid FloatingRateBondFactory.Create with
    floatingRate = FloatingRate with
      instrument = bondInstrument
      description = "Instrument representing units of a floating rate bond"
      floatingRate
      couponSpread
      periodicSchedule
      holidayCalendarIds
      calendarDataProvider = bank
      dayCountConvention
      currency = usdInstrument
      notional
      lastEventTimestamp = initialTimestamp
    observers = Map.fromList pp

```

Compared to the fixed rate bond, notice that this floating rate instrument also has a `referenceRateId`, that specifies which Observations to use in the lifecycle section below.

We also create a bond holding in Bob's account:

```

-- Credit Bob's account with a bond holding
bobRequestCid <- submit bob do
  createCmd CreditAccount.Request with
    account = bobAccount
    instrument = bondInstrument
    amount = 1000000.0
  bobBondHoldingCid <- submit bank do exerciseCmd bobRequestCid CreditAccount.
    Accept

```

Now, we have both an instrument definition and a holding. Let us proceed to lifecycle the bond using Observations, which is the main purpose of this tutorial.

Lifecycle Events and Rule

An *Observation* of a reference rate contains two pieces of information: the interest rate level and the date to which it applies. The rate level can be positive or negative. In our example, we have a negative interest rate:

```

let observations = Map.fromList [(dateToDateClockTime $ date 2019 Jan 16, -0.
  00311)]

observableCid <- toInterfaceContractId <$> submit bank do
  createCmd Observation with
    provider = bank; id = Id referenceRateId; observations; observers = mempty

```

In our case, the bank then creates the observation on the ledger. The *Observation* implements the *NumericObservable* interface, which is used during lifecycleing.

In order to lifecycle a coupon payment, we need a lifecycle rule that defines how to process all time events. We also need a time event corresponding to the date of the first coupon. Both of these are the same as in the previous tutorial using a fixed rate bond, so we will reuse them from there.

Now, we have what we need to actually lifecycle the bond:

```
-- Try to lifecycle the instrument
(lifecycleCid, [effectCid]) <- submit bank do
  exerciseCmd lifecycleRuleCid Lifecycle.Evolve with
    eventCid = firstCouponClockEventCid
    observableCids = [observableCid]
    instrument = bondInstrument
```

The difference compared to the previous tutorial is that here we also pass in the observables to the Evolve choice. They are used to evaluate the reference rate on the relevant fixing date of the coupon payment currently being lifecycled.

The result of this is an effect describing the per-unit asset movements to be executed for bond holders. Each holder can now present their holding to *claim* the effect and instruct settlement of the associated entitlements.

The remaining steps (define a claim rule, claim the effect and settle the entitlements) are identical to the previous tutorial.

Note that the lifecycling process above is not limited to floating rate bonds, which have a reference rate as observable. It also works for other instruments that depend on an underlying asset, for example:

Instrument	Observed variable
Inflation linked bond	Inflation index
Interest rate swap	Reference rate (similar to a floating rate bond)
Asset swap	Reference asset
Credit default swap	Default probability & Recovery rate (two observables)
Vanilla option	Reference asset (often end of day fixing)
Barrier option	Reference asset (often intraday observations)

21.3.3.2 Frequently Asked Questions

Which party should create the observations?

In the simplified scenario for this tutorial, the bank created the observation. In a real-world case, it would probably be the issuer (or a 3rd-party reference data agent) that creates the observations.

21.3.3.3 Summary

You have learned how to create a floating rate bond and how to define observations that define the amount of the coupon payments. The key concepts to take away are:

Observations are required in order to lifecycle some instruments.

Observations are a general concept that can be used to model different kind of payoffs, using various types of underlyings.

Lifecycling instruments with observations works in a very similar manner compared to those without.

21.3.4 Election-based lifecycling (using a callable bond)

This tutorial describes how to define and process Elections. It builds on the previous [Time-based Lifecycling](#) tutorial, which uses a fixed rate bond where all coupons are pre-defined and are paid out as time passes. In contrast, the coupons of a callable bond depend on whether the issuer has called the bond. Hence, a simple time event is not sufficient to define the next state of the instrument. Instead, the lifecycling framework requires an active Election to be made on each call date. This Election is the main topic of the tutorial. Check out the [Lifecycling concepts](#) for more details on time based vs election based evolution of instruments.

In this tutorial, we are going to:

1. create a callable bond instrument and book a holding on it
2. reuse the lifecycle rule and settlement factory from the fixed rate bond tutorial
3. create the election not to call the bond
4. process the election event to produce the effects of a coupon payment
5. instruct settlement by presenting a bond holding
6. settle the resulting batch atomically

21.3.4.1 Run the Script

The code for this tutorial can be executed via the `runCallableBond` script in the `CallableBond.daml` module.

Instrument and Holding

In order to demonstrate the [Election](#) concept, we need a suitable sample instrument. [Callable bonds](#) pay coupons as long as the bond has not been called by the issuer. The [Bond Instrument packages](#) page describes this instrument in more detail. Here, we briefly show how to create the bond instrument using a factory:

```
-- Create a callable bond factory
callableBondFactoryCid <- toInterfaceContractId @CallableBondFactory.I <$>□
←submit bank do
  createCmd CallableBond.Factory with
    provider = bank
    observers = mempty

-- Define an instrument key for the bond
let
```

(continues on next page)

(continued from previous page)

```

bondInstrument = InstrumentKey with
  issuer = bank
  depository = bank
  id = Id "CallableBond"
  version = "0"
  holdingStandard = TransferableFungible

-- Bank creates the bond instrument
callableBondCid <- submit bank do
  exerciseCmd callableBondFactoryCid CallableBondFactory.Create with
    callable = Callable with
      instrument = bondInstrument
      description = "Instrument representing units of a callable bond"
      floatingRate
      couponRate
      capRate
      floorRate
      couponSchedule = periodicSchedule
      noticeDays
      callSchedule = periodicSchedule
      holidayCalendarIds
      calendarDataProvider = bank
      dayCountConvention
      useAdjustedDatesForDcf
      currency = usdInstrument
      notional
      lastEventTimestamp = initialTimestamp
      prevEvents = []
      observers = Map.fromList pp

```

Compared to the fixed rate bond, notice that this callable instrument also has a `callSchedule`, that specifies the dates on which the issuer can call the bond.

We also create a bond holding in Bob's account:

```

-- Credit Bob's account with a bond holding
bobRequestCid <- submit bob do
  createCmd CreditAccount.Request with
    account = bobAccount
    instrument = bondInstrument
    amount = 100000.0
  bobBondHoldingCid <- submit bank do exerciseCmd bobRequestCid CreditAccount.
  Accept

```

Now, we have both an instrument definition and a holding. Let us proceed to lifecycle the bond using Elections, which is the main purpose of this tutorial.

Lifecycle Events and Rule

We start by creating an Election factory, which can be used to create elections:

```
-- Create election factory to allow holders to create elections
electionFactoryCid <- submit bank do
  toInterfaceContractId @ElectionFactory.I <$> createCmd Election.Factory with
    provider = bank
    observers = Map.fromList [("Observers", Set.fromList [bob, bank])]
```

An [Election](#) contains three main pieces of information:

- the election tag (e.g. CALLED)
- who is making the election (e.g. the bank)
- the date to which it applies.

In our example, the bank chooses not to call the bond:

```
-- Create an Election for the first coupon date: do not call the bond.
electionCid <- submit bank do
  exerciseCmd electionFactoryCid ElectionFactory.Create with
    actors = Set.singleton bank
    id = Id "election id"
    description = "election for a callable bond"
    claim = "NOT CALLED"
    electionTime = dateToClockTime $ date 2019 May 15
    electorIsOwner = False
    elector = bank
    counterparty = bank
    instrument = bondInstrument
    amount = 100000.0
    observers = Map.fromList [("Holders", Set.fromList [bank, bob])]
    provider = bank
```

Note the flag `electorIsOwner` above. Since the bank is not the owner of the bond holding, this flag is `False` in our example. On the other hand, if an investor Alice would have had a holding in a puttable bond, the election whether or not to put would have belonged to Alice (the holding owner), so this flag would have been `True`.

Also, note that there is an `amount` in the election above. This allows the elector to create an election for a specific number of holding units.

Now, we have what we need to actually lifecycle the bond. The `Apply` choice is exercised in order to process the election:

```
-- Apply election to generate new instrument version + effects
(newInstrumentKey, [effectCid]) <- submit bank do
  exerciseCmd electionCid Election.Apply with
    observableCids = []
    exercisableCid = coerceInterfaceContractId @Election.Exercisable
    lifecycleRuleCid
```

In order to lifecycle the coupon payment above, we need a lifecycle rule that defines how to process all election events. The lifecycle rule from the previous tutorial can be reused for this, if we first convert it to an `Election.Exercisable`, as described above.

A [Claim Rule](#) allows the elector to claim the effect resulting from the election event:

```
-- Create a new claim rule with the bank as claimer, since it is the bank that
↳ does the election.
lifecycleClaimRuleCid <- toInterfaceContractId @Claim.I <$> submit bank do
  createCmd Claim.Rule with
    provider = bank
    claimers = Set.singleton bank
    settlers = Set.singleton bob
    routeProviderCid
    settlementFactoryCid
    netInstructions = False
```

Note that even though we already had a claim rule in the previous example, we could not reuse it because that one was for the *holding owner* to claim the results, whereas in the case of Election based lifecycling it is the *elector* that should claim them:

```
-- Claim effect
result <- submit bank do
  exerciseCmd lifecycleClaimRuleCid Claim.ClaimEffect with
    claimer = bank
    holdingCids = [bobBondHoldingCid]
    effectCid
    batchId = Id "BondSettlement"
  let [bobInstructionCid, bankInstructionCid, couponInstructionCid] = result.
  ↳ instructionCids
```

The result of this is an effect describing the per-unit asset movements to be executed for bond holders.

The remaining steps (settling the entitlements) are identical to the previous tutorial.

Note that the election process above is not limited to callable bonds. It also works for other instruments that require a manual decision, such as a physically settled option with a manual exercise decision.

21.3.4.2 Frequently Asked Questions

Which party should create the elections?

This depends on the economics of the instrument. For example, in a callable bond, it is the issuer of the bond that has the right to choose whether or not to call the bond on the call dates. On the other hand, in the case of a puttable bond, it would be the investor that can elect to demand early repayment of the bond.

What if a bond can only be called on some coupon dates?

Some instruments can require both time based and election based lifecycling. For example, consider a callable bond that has a quarterly coupon but a call schedule that only allows the bond to be called once a year. In this case, an Election has to be created on the call dates to lifecycle the bond. On the other coupon dates, regular time based lifecycling is required to process the coupon payments.

21.3.4.3 Summary

You have learned how to create a callable bond and how to define Elections to choose whether or not to call the bond. The key concepts to take away are:

Elections are required in order to lifecycle some instruments that require an active choice by one of the stakeholders.

Depending on the economics of the instrument, either the holding owner or the issuer should create the election.

Some instruments require both time based and election based lifecycling.

21.4 Upgrade

This section delves into the processes for upgrading existing contract instances on a Daml ledger. A thorough understanding of the different types of upgrades is essential to choose the most suitable method for various scenarios.

Upgrades are broadly classified into two categories:

Voluntary Upgrades: Voluntary upgrades are similar to an airline offering you the option to upgrade your ticket from economy to business class. The upgrade only happens if you take an action (typically involving making a payment).

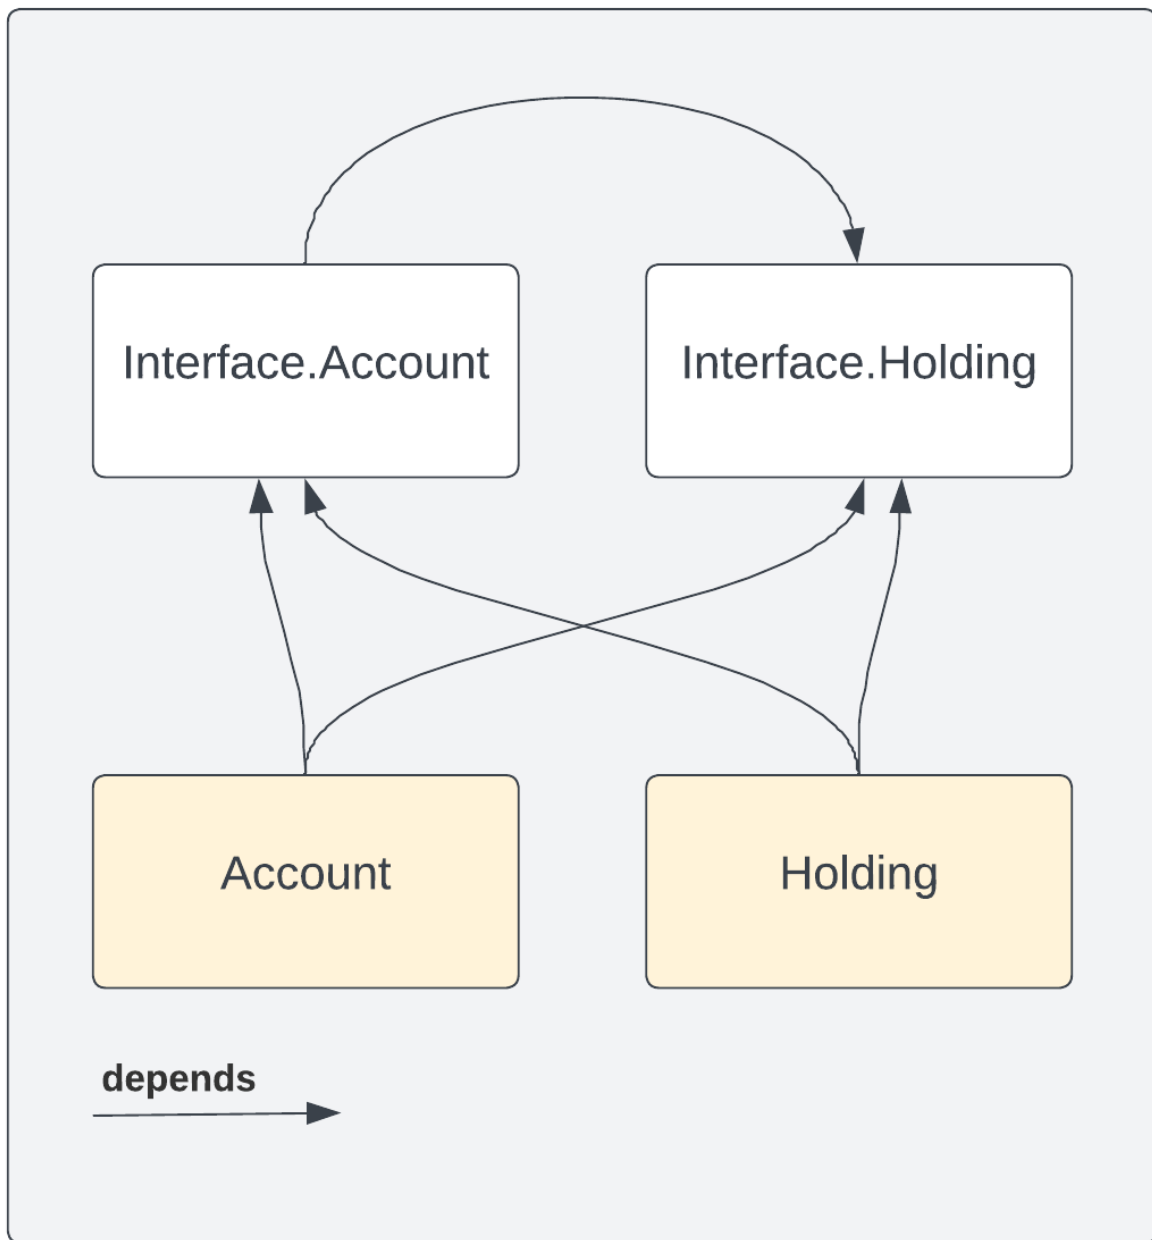

Mandatory Upgrades: In contrast, mandatory upgrades happen inevitably, regardless of your preference. A common example is the automatic updating of smartphone apps. They typically occur *lazily* the next time you use the app. This approach allows software providers to uniformly expand their offerings.

We offer the following tutorials to guide you through the upgrade process:

[Account Upgrade Tutorial](#): This tutorial covers voluntary upgrades. It presents a scenario where a custodian enables clients to voluntarily upgrade their `Account` contracts to a newer version.

[Holding Upgrade Tutorial](#): Here, we walk you through a scenario where a custodian upgrades the `Transferable` holding implementation to a custom, enhanced version, and its `HoldingFactory` accordingly. As a result, existing holding instances (of the `Transferable` holding standard) will be automatically upgraded to the new version during the next transfer. This serves as a practical example of a mandatory upgrade carried out in a lazy manner.

Note that upgrades for `Account` and `Holding` instances can be carried out independently, thanks to the intentional decoupling of their implementation packages in Daml Finance:

21.4.1 Download the Code for the Tutorials

As a prerequisite, make sure that the [Daml SDK](#) is installed on your machine.

Open a terminal and run:

```
daml new finance-upgrades --template=finance-upgrades
```

This creates a new folder with contents from our template. Navigate to the `finance-upgrades` folder and then run the following to download the required Daml Finance packages:

```
./get-dependencies.sh
```

or, if you are using Windows

```
./get-dependencies.bat
```

Finally, you can start Daml Studio to inspect the code and run the project's scripts:

```
daml studio
```

21.4.2 Account Upgrade

This tutorial presents a scenario where a custodian offers its clients the option to *voluntarily* upgrade their old [Account](#) contracts to a new version. The focus is on demonstrating the process of such a voluntary upgrade.

We are going to:

1. Introduce `MyAccount`, a custom account implementation for the custodian. It differs from the standard Daml Finance [Account](#) implementation in that it does not implement the [Lockable](#) interface, making it a non-freezable account.
2. Prevent the custodian from creating old [Account](#) instances, by archiving its existing [AccountFactory](#).
3. Instantiate a new account factory, `MyAccountFactory`, which can create `MyAccount` instances.
4. Provide a `MyAccountUpgradeRule` instance for clients, permitting them to upgrade their existing [Account](#) instances to new `MyAccount` instances.
5. Upgrade the accounts for the clients.

21.4.2.1 Run the Script

You can run this tutorial using the `runUpgradeAccount` script found in the `UpgradeAccount.daml` module. Let us examine it step-by-step.

Setup

The script starts off with `runSetupAccountsAndHoldings` which sets up the necessary parties (a custodian Bank and its clients, Alice and Bob), an account factory (used for creating accounts) for the Bank, and accounts for both Alice and Bob. Additionally, it creates a holding for Alice. Since the holding refers to its account by key, which remains unchanged, it does not require an upgrade when the account is upgraded:

```
SetupState
{ bank
; bankAccountFactoryCid
; alice
; aliceAccount
; bob
; bobAccount
; allClients
} <- runSetupAccountsAndHoldings
```

Initially, the accounts and the account factory are of the old version. The new implementations, `MyAccount` and `MyAccountFactory`, can be found in the `MyAccount.daml` module.

Create a New Account Factory

To prevent the creation of accounts of the old implementation, the first step involves archiving the Bank's existing account factory:

```
submit bank do archiveCmd bankAccountFactoryCid
```

Next, we instantiate a `MyAccountFactory` responsible for creating `MyAccount` instances:

```
submit bank do createCmd MyAccountFactory with provider = bank; observers =  
↳ allClients
```

Provide an Upgrade Rule

To offer the clients to upgrade their existing account to a `MyAccount` instance, we instantiate a `MyAccountUpgradeRule` contract (which is also part of the `MyAccount.daml` module):

```
cid <- submit bank do createCmd MyAccountUpgradeRule with custodian = bank;  
↳ observers = allClients
```

Clients Upgrade

Following this, we let both Alice and Bob upgrade to the new account version:

```
submit alice do exerciseCmd cid UpgradeToMyAccount with account = aliceAccount  
submit bob do exerciseCmd cid UpgradeToMyAccount with account = bobAccount
```

21.4.2.2 Summary

Upon completing this tutorial, you should have a solid understanding of how to manage voluntary upgrades. The essential steps include:

- Replacing the old factory with a new, updated version.
- Introduce a rule contract that enables users to transition from the old to the new version, provided they are willing to do so.

In our next tutorial, we'll explore the process of upgrading holdings in a lazy manner.

21.4.3 Holding Upgrade

This tutorial demonstrates how a custodian can upgrade their holding implementation for the *Transferable* holding standard to a custom, extended version in a *lazy* manner. Specifically, the upgrade occurs seamlessly during a client's transfer action.

We are going to:

1. Introduce a new holding implementation, `MyTransferable`, which extends the Daml Finance *Transferable* holding implementation. This new implementation differs in that it creates a `MyTransferableTransferEvent` contract instance with each transfer.
2. Replace the existing *HoldingFactory* instance of the custodian with a new, compatible `MyHoldingFactory` for the `MyTransferable` holding implementation.
3. Demonstrate that an upgrade happens upon a transfer of an old holding.

21.4.3.1 Run the Script

You can execute this tutorial using the `runUpgradeHolding` script found in the `UpgradeHolding.daml` module. We'll examine the script step-by-step to demonstrate how it works in practice.

Setup

The script begins with `runSetupAccountsAndHoldings`, initializing parties (a custodian Bank and its clients, Alice and Bob), an account factory for the Bank, accounts for Alice and Bob, a holding factory for the Bank, and a holding for Alice:

```
SetupState
{ bank
; bankHoldingFactory
; alice
; aliceAccount
; aliceTransferableCid
; bob
; bobAccount
; allClients
} <- runSetupAccountsAndHoldings
```

Initially, both the holding and holding factory are in the old version. The new `MyTransferable` and `MyHoldingFactory` implementations are available in the `MyHolding.daml` module.

Create a New Holding Factory

To avoid creating holdings with the old implementation, we archive the Bank's holding factory:

```
removeHoldingFactory bankHoldingFactory
```

Subsequently, we create a new holding factory with the same key for the Bank:

```
myHoldingFactory <- createMyHoldingFactory $
  MyHoldingFactory with
    provider = bank
```

(continues on next page)

(continued from previous page)

```
id = Id "Holding Factory"
observers = allClients
```

Note on Upgrade Rule

Unlike the account upgrade tutorial, this process does not require an upgrade rule contract.

Client Upgrades

We let Alice transfer her holding to Bob:

```
Some _ <- queryContractId alice $ fromInterfaceContractId @Transferable.T
↪aliceTransferableCid
bobHoldingCid <- submit alice do
  exerciseCmd aliceTransferableCid
    Transferable.Transfer with
      actors = singleton alice
      newOwnerAccount = bobAccount
Some _ <- queryContractId bob $ fromInterfaceContractId @MyTransferable
↪bobHoldingCid
```

As a result, Alice's existing holding is debited and Bob is credited a holding of the new version.

21.4.3.2 Summary

Upon completing this tutorial, you should have a clear understanding of how to implement lazy upgrades for holdings. The essential points to remember are:

- The old holding factory is to be replaced with a new one having the same key.
- Upgrades of holdings occur automatically during debiting and crediting actions, such as during transfers and settlement processes, facilitating a lazy upgrade approach.

21.5 Payoff Modeling

This section contains an introduction to the Daml Finance [Generic Instrument](#), which provides a flexible framework to structure custom payoffs and lifecycle them on the ledger.

The Generic Instrument encapsulates the [Contingent Claims](#) library, which models the economic terms of an instrument based on its future cashflows and other contractual events.

The tutorials introduce the Contingent Claims modeling framework in a practical way and give you the tools to

- structure financial instruments such as bonds, swaps, options, and other derivatives
- lifecycle the instruments on-ledger to calculate pending payments

The following tutorials are available:

- The [Basic Builders](#) tutorial introduces the basic Contingent Claims builders.

The [Observations](#) tutorial shows how to model market observables, such as interest rates or equity spot prices.

21.5.1 Download the Code for the Tutorials

As a prerequisite, make sure that the [Daml SDK](#) is installed on your machine.

Open a terminal and run:

```
daml new finance-payoff-modeling --template=finance-payoff-modeling
```

This creates a new folder with contents from our template. Navigate to the `finance-payoff-modeling` folder and then run the following to download the required Daml Finance packages:

```
./get-dependencies.sh
```

or, if you are using Windows

```
./get-dependencies.bat
```

Finally, you can start Daml Studio to inspect the code and run the project's scripts:

```
daml studio
```

21.5.2 Basic Builders

This tutorial introduces the basic claim constructors and shows how to use them to describe a payoff in terms of the future cashflows and other effects between the claim's owner and their counterparty. At the end of this section, you should be able to model payoffs such as fixed rate bonds and FX forwards.

You can use the `PayoffBuilder` module to follow along and test the claims described below. When you run the `runCreateAndLifecycle` script, it will

- create a Daml Finance Generic instrument wrapping your input claim
- lifecycle the instrument at the specified dates
- print out pending cashflows

21.5.2.1 Builders

Zero

The `zero` constructor is used to indicate the absence of cashflows and other contractual events. We can setup this very simple initial payoff as follows

```
c = zero  
  
acquisitionDate = date 2023 Aug 01
```

The acquisition date is used to track the date at which two parties enter the contract and it is a required input to each claim.

One

The `one` constructor is used to deliver to the owner of the contract one unit of a specified instrument. For instance, the claim

```
c = one "USD"

acquisitionDate = date 2023 Aug 01
```

gives the owner an `immediate` right to receive one unit of the `USD` instrument.

We can verify that by lifecycling the claim: we define a set of lifecycle dates

```
lifecycleDates =
[
  date 2023 Aug 01
, date 2023 Aug 03
]
```

and run the script to obtain

```
 "--- EFFECT on 2023-08-01 ---"
"TARGET INSTRUMENT : MyClaim version 0"
"RECEIVING"
" => 1.0 USD"
"GIVING"
```

When we lifecycle as of `01 Aug 2023` a payment of `1USD` is received by the owner. This is recorded in the corresponding `Effect` contract. The claim then becomes worthless (it becomes the `zero` claim) and any subsequent lifecycling yields no additional effects.

Scale

The `scale` constructor is used to multiply a claim's effects by a certain factor.

```
c = scale (Const 100.0) $ one "USD"

acquisitionDate = date 2023 Aug 01
```

As expected, lifecycling now yields

```
 "--- EFFECT on 2023-08-01 ---"
"TARGET INSTRUMENT : MyClaim version 0"
"RECEIVING"
" => 100.0 USD"
"GIVING"
```

Give, And

The `and` constructor is used to sum effects from multiple sub-claims.

`give` is used to exchange rights and obligations, flipping the direction of effects.

We can define a very simple FX trade as follows, where the owner receives EUR in exchange for USD.

```
c1 = scale (Const 90.0) $ one "EUR"
c2 = scale (Const 100.0) $ one "USD"
c = c1 `and` (give c2)

acquisitionDate = date 2023 Aug 01
```

When the claim is lifecycled, we obtain

```
"--- EFFECT on 2023-08-01 ---"
"TARGET INSTRUMENT : MyClaim version 0"
"RECEIVING"
" => 90.0 EUR"
"GIVING"
" => 100.0 USD"
```

When you want to additively combine more than two claims, you can use the `andList` constructor.

Warning: By default, the `and` operator is the [function](#) defined in the Daml standard library. To use the claim constructor instead, use a qualified import. Alternatively, you can hide the function from the standard library by using the syntax

```
import Prelude hiding (and)
```

The same applies to the `or` operator, which is not covered in this section.

When

The `when` constructor is used to introduce a time shift, delaying the acquisition of another claim to a point in the future when a certain predicate is met. For instance, the claim

```
maturity = date 2023 Aug 31
c = when (at maturity) $ one "USD"

acquisitionDate = date 2023 Aug 01
```

pays one USD once the maturity date is reached, but not before.

When this is lifecycled before maturity, no effect is generated. On the other hand, once we reach maturity we observe

```
"--- EFFECT on 2023-08-31 ---"
"TARGET INSTRUMENT : MyClaim version 0"
"RECEIVING"
" => 1.0 USD"
"GIVING"
```

The `at` function is used to construct a predicate which becomes `True` exactly at the input date, triggering the acquisition of the sub-claim `one "USD"`.

21.5.2.2 Structuring financial instruments

Equipped with these basic claim builders, we can already structure a variety of real-world financial instruments.

Fixed Rate Bond

A fixed rate bond pays a fixed interest rate over its term and repays the principal amount at maturity. This can be represented as follows

```
interestAmount = Const 50.0
principal = Const 100000.0
c = andList [
  when (at d1) $ scale interestAmount $ one "USD"
  , when (at d2) $ scale interestAmount $ one "USD"
  , when (at maturity) $ scale (interestAmount + principal) $ one "USD"
]
```

for $d1 \leq d2 \leq \text{maturity}$.

FX Forward

As an exercise, try to model an FX Forward, which is a contractual agreement between two parties to exchange a pair of currencies at a set rate on a future date.

21.5.2.3 Summary

You have learned the basic claim constructors and are now able to structure some real-world financial instruments. The next tutorial will introduce `Observations`, which are used to model time-dependent market observables, such as stock prices and interest rates fixings.

21.5.3 Observations

21.5.3.1 Equity forward payoff

The payoff of financial derivatives depends on the performance of a certain underlying in the future. As an example, consider an equity forward contract where a party agrees to purchase one stock of Apple at a predetermined date and price in the future. The contract buyer will make a profit if the market price of the stock is greater than the purchase price they pay (and make a loss otherwise).

This payoff can be written as follows

```
maturity = date 2023 Aug 31
c = when (at maturity) $ scale (Observe "AAPL" - Const 195.0) $ one "USD"

acquisitionDate = date 2023 Aug 01
```

In this example, the predetermined purchase price (strike price) is 195 USD.

Observe "AAPL" is used to represent the time-dependent market price of Apple, which is unknown at trade inception.

When lifecycling the claim at maturity, we must provide the observed market value for the observable AAPL in order to resolve the claim's cashflows and other effects.

```
observations =
[
  ("AAPL", [(date 2023 Aug 31, 200.0)])
]
```

This yields the expected payoff

```
"--- EFFECT on 2023-08-31 ---"
"TARGET INSTRUMENT : MyClaim version 0"
"RECEIVING"
" => 5.0 USD"
"GIVING"
```

You can change the stock's observed value in the script and see how this impacts the generated cashflows.

As you might have realised, the multiplying factor within a `scale` builder does not have to be a constant or deterministic quantity. It is a generic `Observation`, which is a combination of known amounts (built with `Const`) and market observables (built with `Observe`). These building blocks can be combined together using standard algebraic operations (+, -, *, /).

In the example above, once the maturity date is reached the sub-claim `scale (Observe "AAPL" - Const 195.0) $ one "USD"` is acquired and the value of the observation is looked up in the table for that maturity date.

21.5.3.2 Floating Rate Note

There are cases where we want to explicitly specify the date at which a market observable is evaluated. Take for example the case of a Floating Rate Note, which is a financial instrument that pays a floating coupon based on an interest rate value observed a few days earlier.

An example of such payoff is the following

```
maturity = date 2023 Aug 31
observation = ObserveAt "USD_LIBOR_3M" (date 2023 Aug 10) * Const 1000000.0
c = when (at maturity) $ scale observation $ one "USD"

acquisitionDate = date 2023 Aug 01
```

where

we observe the value of the 3 month US Dollar LIBOR rate on 10 Aug 2023
 we pay a coupon for that rate on 31 Aug 2023

The `ObserveAt` observation builder is used to specify when the rate should be observed. In order to lifecycle the claim at maturity we must include the rate observation in the table

```
observations =  
[  
  ("USD_LIBOR_3M", [(date 2023 Aug 10, 0.0563)])  
]
```

which then yields to the expected payout

```
"--- EFFECT on 2023-08-31 ---"  
"TARGET INSTRUMENT : MyClaim version 0"  
"RECEIVING"  
" => 56300.0 USD"  
"GIVING"
```

21.5.3.3 Interest Rate Swap

As an exercise, try to model

- a fixed-for-floating interest rate swap, where the claim owner receives coupons based on a floating rate in exchange for fixed rate coupons.
- a basis rate swap, where the owner receives coupons based on 3 month US Dollar LIBOR and pays coupons based on 6 month US Dollar LIBOR to their counterparty

21.5.3.4 Summary

You now know how to setup payoffs containing complex time-dependent market observables. You have the tools to model a large set of financial products, such as forwards and most interest rate swap variations.

21.6 Advanced Topics

This section covers some advanced Daml Finance topics, helping you model complex use-cases and scenarios.

The following tutorials are available:

- The [Intermediated Lifecycling](#) tutorial demonstrates how to lifecycle an instrument with an intermediary party between the issuer and the investor.
- The [Contingent Claims Instrument](#) tutorial describes how to leverage the Contingent Claims library to lifecycle custom instrument implementations.
- The [Date utility](#) tutorial shows you how to use the calendar, schedule, and day count utility functions (for example, to create your own instruments).

21.6.1 Intermediated Lifecycling of an Instrument

This tutorial describes the *lifecycling* flow of an instrument with an intermediary party between the issuer and the investor. We will use the a *Generic Instrument*, but the same concepts apply to other instrument types as well.

We will illustrate the following steps:

1. Creating a Generic Instrument modeling a fixed rate bond
2. Defining an intermediated settlement route
3. Defining a suitable lifecycle event
4. Lifecycling the instrument
5. Non-atomic settlement of the lifecycle effects
6. Atomic settlement of the lifecycle effects

To follow the script used in this tutorial, you can [clone the Daml Finance repository](#). In particular, the file `Instrument/Generic/Test/Intermediated/BondCoupon.daml` is the starting point of this tutorial. It contains an example for both non-atomic and atomic settlement of lifecycle effects. In this tutorial we will focus on the non-atomic settlement, but we will mention atomic settlement towards the end.

21.6.1.1 Create the Instrument

We start by using a *Generic Instrument* to model a fixed rate bond paying a 4% p.a. coupon with a 6M coupon period.

21.6.1.2 Define an Intermediated Settlement Route

In the case of intermediated lifecycling, we need to define a settlement route for the bond instrument, which depends on the account structure:

```
{-
Bond (security) account structure :

    Issuer
    |
    CSD
    |
    Investor
-}
let
  route =
    ( bondLabel
    , Hierarchy with
      rootCustodian = issuer
      pathsToRootCustodian = [[investor, csd]]
    )
```

Similarly, we define a settlement route for the cash instrument instrument:

```
{-
Cash account structure :

    Central Bank
```

(continues on next page)

(continued from previous page)

```

      /   |   \
    CSD  Issuer Bank
           \
           Investor

-}
route =
  ( label
  , Hierarchy with
    rootCustodian = centralBank
    pathsToRootCustodian = [[investor, bank], [csd], [issuer]]
  )

```

21.6.1.3 Define a Lifecycle Event

Since the bond pays a coupon twice a year, payment is a time-based event. The requirement to pay the coupon is governed by actual time. However, in a trading and settlement system, it is useful to be able to control the time variable, in order to simulate previous/future payments, or to have some flexibility regarding when to process events.

Because of this, the issuer defines a clock update event contract, which signals that a certain time has been reached:

```

-- create clock update event
clockEventCid <- createClockUpdateEvent (Set.singleton issuer) today mempty

```

21.6.1.4 Lifecycle the Bond Instrument

Using the [Lifecycle](#) interface, the CSD creates a lifecycle rule contract:

```

-- Create a lifecycle rule
lifecycleRuleCid <- toInterfaceContractId @Lifecycle.I <$> submit csd do
  createCmd Lifecycle.Rule with
    providers = Set.singleton csd
    observers = mempty
    lifecycler = issuer
    id = Id "LifecycleRule"
    description = "Rule to lifecycle a generic instrument"

```

The issuer of the bond is responsible for initiating the lifecycling of the coupon payment, by exercising the `Evolve` choice on the coupon date:

```

-- Try to lifecycle the instrument
(, [effectCid]) <- submit issuer do
  exerciseCmd lifecycleRuleCid Lifecycle.Evolve with
    eventCid = clockEventCid
    observableCids = []
    instrument = bondInstrument

```

This internally uses the [Event](#) interface. In our case, the event is a clock update event, since the coupon payment is triggered by the passage of time.

The return type of `effectCid` is an [Effect](#) interface. It will contain the effect(s) of the lifecycling, in this case a coupon payment. If there is nothing to lifecycle, for example because there is no coupon to be paid today, this would be empty.

21.6.1.5 Non-atomic Settlement

In order to process the effect(s) of the lifecycling (in this case: pay the coupon), we need to create settlement instructions. In the non-atomic case, this is done in two steps.

First, there is the settlement between the issuer and the CSD. By using the `EffectSettlementService` template, the issuer can claim and settle the lifecycling effects in one step by exercising the `ClaimAndSettle` choice:

```
-- Setup settlement contract between issuer and CSD
-- In order for the workflow to be successful, we need to disclose the CSD's
-- cash account to the
-- Issuer.
Account.submitExerciseInterfaceByKeyCmd @Disclosure.I [csd] [] csdCashAccount
  Disclosure.AddObservers with
    disclosers = Set.singleton csd; observersToAdd = ("Issuer", Set.singleton
--issuer)

settle1Cid <- submitMulti [csd, issuer] [] do
  createCmd EffectSettlementService with
    csd
    issuer
    instrumentId = bondInstrument.id
    securitiesAccount = csdAccountAtIssuer
    issuerCashAccount
    csdCashAccount
    settlementRoutes = routes

-- CSD claims and settles effect against issuer
(effectCid, newInstrumentHoldingCid, [cashHolding]) <- submitMulti [issuer]
--[publicParty] do
  exerciseCmd settle1Cid ClaimAndSettle with
    instrumentHoldingCid = csdBondHoldingCid; cashHoldingCid =
--issuerCashHoldingCid; effectCid
```

Then, there is the settlement between the CSD and the investor. We start by creating a settlement factory:

```
-- investor claims effect against CSD
routeProviderCid <- toInterfaceContractId <$> submit csd do
  createCmd IntermediatedStatic with
    provider = csd; observers = Set.singleton investor; paths = routes

settlementFactoryCid <- submit csd do
  toInterfaceContractId <$> createCmd Factory with
    provider = csd; observers = Set.singleton investor
```

Settlement instructions are created by using the [Claim](#) interface and exercising the `ClaimEffect` choice:

```

lifecycleClaimRuleCid <- toInterfaceContractId @Claim.I <$> submit csd do
  createCmd Claim.Rule with
    provider = csd
    claimers = Set.fromList [csd, investor]
    settlers
    routeProviderCid
    settlementFactoryCid
    netInstructions = False

result <- submit csd do
  exerciseCmd lifecycleClaimRuleCid Claim.ClaimEffect with
    claimer = csd
    holdingCids = [investorBondHoldingCid]
    effectCid
    batchId = Id "CouponSettlement"

```

Claiming the effect has two consequences:

- the investor's holding is upgraded to a new instrument version (where the coupon has been paid)
- settlement instructions are generated in order to process the coupon payment

Finally, the settlement instructions are allocated, approved and then settled.

```

let
  [investorBondInstructionCid, csdBondInstructionCid, csdCashInstructionCid,
   bankCashInstructionCid] = result.instructionCids

-- Allocate instructions
(investorBondInstructionCid, _) <- submit investor do
  exerciseCmd investorBondInstructionCid Instruction.Allocate with
    actors = Set.singleton investor; allocation = Pledge investorBondHoldingCid
(csdBondInstructionCid, _) <- submit csd do
  exerciseCmd csdBondInstructionCid Instruction.Allocate with
    actors = Set.singleton csd; allocation = CreditReceiver
(csdCashInstructionCid, _) <- submit csd do
  exerciseCmd csdCashInstructionCid Instruction.Allocate with
    actors = Set.singleton csd; allocation = Pledge cashHolding
(bankCashInstructionCid, _) <- submit bank do
  exerciseCmd bankCashInstructionCid Instruction.Allocate with
    actors = Set.singleton bank; allocation = CreditReceiver

-- Approve instructions
investorBondInstructionCid <- submit csd do
  exerciseCmd investorBondInstructionCid Instruction.Approve with
    actors = Set.singleton csd; approval = DebitSender
csdBondInstructionCid <- submit investor do
  exerciseCmd csdBondInstructionCid Instruction.Approve with
    actors = Set.singleton investor; approval = TakeDelivery
investorSecuritiesAccount
csdCashInstructionCid <- submit bank do
  exerciseCmd csdCashInstructionCid Instruction.Approve with
    actors = Set.singleton bank; approval = TakeDelivery bankCashAccount
bankCashInstructionCid <- submit investor do
  exerciseCmd bankCashInstructionCid Instruction.Approve with
    actors = Set.singleton investor; approval = TakeDelivery investorCashAccount

```

(continues on next page)

(continued from previous page)

```
-- Settle batch
[investorCashHoldingCid, bankCashHoldingCid, investorBondHoldingCid] <-
  submitMulti (Set.toList settlers) [publicParty] do
    exerciseCmd result.batchCid Batch.Settle with actors = settlers
```

Following settlement, the investor receives a cash holding for the due coupon amount.

21.6.1.6 Atomic Settlement

In the non-atomic settlement case above, settlement was done in two steps: first from issuer to CSD and then from CSD to investor. In atomic settlement, this is done in one step.

The first part of the process is very similar. The first important difference is when the CSD exercises the `ClaimEffect` choice, where the bond holdings of both the CSD and the investor are provided:

```
result <- submit csd do
  exerciseCmd lifecycleClaimRuleCid Claim.ClaimEffect with
    claimer = csd
    holdingCids = [csdBondHoldingCid, investorBondHoldingCid]
    effectCid
    batchId = Id "CouponSettlement"
```

There are now more settlement instructions (both from CSD to issuer and from issuer to CSD):

```
let
  [
    csdBondInstructionCid1      -- old bond from CSD to issuer
    , investorBondInstructionCid -- old bond from investor to CSD
    , issuerBondInstructionCid  -- new bond from issuer to CSD
    , csdBondInstructionCid2    -- new bond from CSD to investor
    , issuerCashInstructionCid  -- coupon payment from issuer to CSD
    , csdCashInstructionCid     -- coupon payment from CSD to investor's bank
    , bankCashInstructionCid    -- coupon payment from investor's bank to
  ] = result.instructionCids
↪ investor
```

These will have to be allocated, approved and settled similarly to the non-atomic case above. See the file [Instrument/Generic/Test/Intermediated/BondCoupon.daml](#) for full details.

21.6.1.7 Frequently Asked Questions

What if one party wants to cancel the settlement?

The parties who sign the `Batch` contract (the instructor and consenters) can exercise the `Cancel` choice of the `Batch` to cancel all associated `Instructions` atomically.

Settlement can also be obstructed if the responsible parties do not fully allocate and approve the settlement instructions.

21.6.2 Leverage Contingent Claims in Custom Instrument Implementations

They [Payoff Modeling tutorial](#) introduces the [Contingent Claims](#) modeling framework in the context of the [Generic Instrument](#). In this chapter, we will see how the library can instead be used to lifecycle custom instrument implementations. The [Bond](#) and [Swap](#) instruments, for example, leverage Contingent Claims behind the scenes to calculate pending coupon payments.

Let us explore in detail how the [fixed rate bond instrument](#) is implemented in Daml Finance. The goal is for you to learn how to implement and lifecycle your own instrument template, should you need an instrument type that is not already implemented in the library.

To follow the code snippets used in this tutorial in Daml Studio, you can clone the [Daml Finance repository](#) and take a look at how the [Bond Instrument template](#) is implemented. In order to see how lifecycling is performed, you can run the script in the [Instrument/Bond/Test/FixedRate.daml](#) file.

21.6.2.1 Template Definition

We start by defining a new template for the instrument. Here are the fields used for the fixed rate instrument:

```
-- | This template models a fixed rate bond.
-- It pays a fixed coupon rate at the end of every coupon period.
template Instrument
  with
    depository : Party
      -- ^ The depository of the instrument.
    issuer : Party
      -- ^ The issuer of the instrument.
    id : Id
      -- ^ The identifier of the instrument.
    version : Text
      -- ^ The instrument's version.
    holdingStandard : HoldingStandard
      -- ^ The holding standard for holdings referencing this instrument.
    description : Text
      -- ^ A description of the instrument.
    couponRate : Decimal
      -- ^ The fixed coupon rate, per annum. For example, in case of a "3.5% p.a.
↪coupon" this should
      -- be 0.035.
    periodicSchedule : PeriodicSchedule
      -- ^ The schedule for the periodic coupon payments.
    holidayCalendarIds : [Text]
      -- ^ The identifiers of the holiday calendars to be used for the coupon
↪schedule.
    calendarDataProvider : Party
      -- ^ The reference data provider to use for the holiday calendar.
    dayCountConvention : DayCountConventionEnum
      -- ^ The day count convention used to calculate day count fractions. For
↪example: Act360.
    currency : InstrumentKey
      -- ^ The currency of the bond. For example, if the bond pays in USD this
↪should be a USD cash
      -- instrument.
    notional : Decimal
```

(continues on next page)

(continued from previous page)

```

-- ^ The notional of the bond. This is the face value corresponding to one
↪unit of the bond
-- instrument. For example, if one bond unit corresponds to 1000 USD,
↪this should be 1000.0.
observers : PartiesMap
-- ^ The observers of the instrument.
lastEventTimestamp : Time
-- ^ (Market) time of the last recorded lifecycle event. If no event has
↪occurred yet, the
-- time of creation should be used.

```

These template variables describe the economic terms of a fixed rate bond.

21.6.2.2 The Claims Interface

We now need to map the template variables to a [Contingent Claims](#) tree, the internal representation we wish to use for lifecycling. Note that the Contingent Claims tree is not a part of the template above, instead it will be created dynamically upon request.

In order to do that, we implement the [Claims interface](#). This interface provides access to a generic mechanism to process coupon payments and redemptions. It will work in a similar way for the majority of instrument types, regardless of their specific economic terms.

Here is a high level implementation of the [Claims interface](#):

```

interface instance Claim.I for Instrument where
  view = Claim.View with acquisitionTime = dateToDateClockTime $
↪daysSinceEpochToDate 0
  getClaims Claim.GetClaims{actor} = do
    -- get the initial claims tree (as of the bond's acquisition time)
    let getCalendars = getHolidayCalendars actor calendarDataProvider
      (schedule, _) <- rollSchedule getCalendars periodicSchedule
↪holidayCalendarIds
    let
      useAdjustedDatesForDcf = True
      ownerReceives = True
      fxAdjustment = 1.0
      couponClaims = createFixRatePaymentClaims dateToDateClockTime schedule
↪periodicSchedule
      useAdjustedDatesForDcf couponRate ownerReceives dayCountConvention
↪notional currency
      redemptionClaim = createFxAdjustedPrincipalClaim dateToDateClockTime
↪ownerReceives
      fxAdjustment notional currency periodicSchedule.terminationDate
      pure [couponClaims, redemptionClaim]

```

The `getClaims` function is where we define the payoff of the instrument.

First, we calculate the coupon payment dates by rolling out a periodic coupon schedule.

The payment dates are then used to build claim sub-trees for the coupon payments.

A claim sub-tree for the final redemption is also created.

Finally, the coupon and redemption sub-trees are joined. Together, they yield the desired economic terms for the bond.

How to define the redemption claim

The redemption claim depends on the currency and the maturity date of the bond.

```
-- | Create an FX adjusted principal claim.
-- This can be used for both FX swaps (using the appropriate FX rate) and single
  ↳ currency bonds
-- (setting the FX rate to 1.0).
createFxAdjustedPrincipalClaim : (Date -> Time) -> Bool -> Decimal -> Decimal ->
  ↳ Deliverable ->
    Date -> TaggedClaim
createFxAdjustedPrincipalClaim dateToTime ownerReceives fxRateMultiplier notional
  cashInstrument valueDate =
  let
    fxLegClaimAmount = when (TimeGte valueDate)
      $ scale (Const fxRateMultiplier)
      $ scale (Const notional)
      $ one cashInstrument
    fxLegClaim = if ownerReceives then fxLegClaimAmount else give fxLegClaimAmount
  in
    prepareAndTagClaims dateToTime [fxLegClaim] "Principal payment"
```

Keywords like *when*, *scale*, *one* and *give* should be familiar from the [Payoff Modeling tutorial](#). *TimeGte* is just a synonym for *at*.

The *ownerReceives* flag is used to indicate whether the owner of a holding on the bond is meant to receive the redemption payment. When this is set to false, the holding custodian will be entitled to the payment.

How to define the coupon claims

The coupon claims are a bit more complicated to define. We need to take a schedule of adjusted coupon dates and the day count convention into account.

```
createFixRatePaymentClaimsList : Schedule -> PeriodicSchedule -> Bool -> Decimal -
  ↳ Bool ->
    DayCountConventionEnum -> Decimal -> Deliverable -> [C]
createFixRatePaymentClaimsList schedule periodicSchedule useAdjustedDatesForDcf
  ↳ couponRate
  ownerReceives dayCountConvention notional cashInstrument =
  let
    couponDatesAdjusted = map (.adjustedEndDate) schedule
    couponAmounts = map (\p ->
      couponRate *
      (calcPeriodDcf dayCountConvention p useAdjustedDatesForDcf
        periodicSchedule.terminationDate periodicSchedule.frequency)
    ) schedule
    couponClaimAmounts = andList $
      zipWith
        (\d a ->
          when (TimeGte d) $ scale (Const a) $ scale (Const notional) $ one
        ) couponDatesAdjusted couponAmounts
  in
    [if ownerReceives then couponClaimAmounts else give couponClaimAmounts]
```

For each coupon period, we calculate the adjusted end date and the actual coupon amount. We then create each coupon claim in a way similar to the redemption claim above.

21.6.2.3 Evolving the Instrument over time

The bond instrument gives the holder the right to receive future coupons and the redemption amount. At issuance, all coupons are due. However, after the first coupon is paid, the holder of the instrument is no longer entitled to receive it again. The `lastEventTimestamp` field in our template is used to keep track of the latest executed coupon payment.

Evolution of the instrument over time (and calculation of the corresponding lifecycle effects) can be performed using the [Lifecycle.Rule](#) template provided in the [Daml.Finance.Claims.V3](#) package. This rule is very generic and can be used for all instruments that implement the [Claims interface](#).

Let us break its implementation apart to describe what happens in more detail:

First, we retrieve the claim tree corresponding to the initial state of the instrument. We do so by fetching the `Claims` interface we defined for the template.

```
claimInstrument <- fetchInterfaceByKey @BaseInstrument.R instrument
```

By using the `lastEventTimestamp` (in our case: the last time a coupon was paid), we can now fast forward the claim tree to the current instrument state.

```
-- Recover claims tree as of the lastEventTimestamp. For a bond, this just
↳requires
-- lifecycling as of the lastEventTimestamp.
dynamicInstrumentView <- BaseInstrument.exerciseInterfaceByKey
↳@DynamicInstrument.I
  instrument
  lifecycler
  DynamicInstrument.GetView with viewer = lifecycler

-- fast-forward the claims tree to the current version by replaying the
↳previous events
let
  prevEvents = dynamicInstrumentView.prevEvents <>
    [timeEvent dynamicInstrumentView.lastEventTimestamp]
  claims <- fst <$> lifecycle lifecycler observableCids claimInstrument
↳prevEvents
```

Finally, we lifecycle the current instrument state to calculate pending effects. If there are such effects (for example when a coupon payment is due), we create a [Lifecycle Effect](#) for it, which can then be claimed and settled.

```
evolve Lifecycle.Evolve{eventCid; observableCids; instrument} = do
  v <- view <$> fetch eventCid

  -- Fast-forward the instrument from inception to the timestamp of the
↳last event.
  -- Then, perform a time-based lifecycling according to the current
↳event.
  (remaining, pending, claims, claimInstrument, dynamicInstrumentView)
↳<-
    fastForwardAndLifecycle instrument observableCids v.eventTime
↳lifecycler
```

(continues on next page)

(continued from previous page)

```

let
  pendingAfterNetting = netOnTag pending
  (otherConsumed, otherProduced) = splitPending pendingAfterNetting
  if remaining == claims && null pendingAfterNetting then
    pure (None, [])
  else do
    let
      currentKey = BaseInstrument.getKey $ toInterface claimInstrument
      newKey = currentKey with version = sha256 $ mconcat [show v.
→eventTime, show remaining]
      producedInstrument = if isZero' remaining then None else Some□
→newKey
      tryCreateNewInstrument lifecycler dynamicInstrumentView.prevEvents□
→v.eventTime None instrument
      newKey
      effectCid <- toInterfaceContractId <$> create Effect with
        providers = singleton currentKey.issuer
        id = v.id
        description = v.description
        targetInstrument = currentKey
        producedInstrument
        otherConsumed
        otherProduced
        settlementTime = Some v.eventTime
        observers = (.observers) . view $ toInterface @Disclosure.I□
→claimInstrument
      pure (Some newKey, [effectCid])

```

21.6.2.4 The Dynamic.Instrument Interface

In the `tryCreateNewInstrument` part above, we create a new version of the instrument containing the updated `lastEventTimestamp` (and also including all previous events up until now). This is done by exercising the `CreateNewVersion` choice of the `Dynamic.Instrument` interface:

```

BaseInstrument.exerciseInterfaceByKey @DynamicInstrument.I
  oldKey
  actor
  DynamicInstrument.CreateNewVersion with
    lastEventTimestamp = eventTime
    prevEvents = case electionData of
      None -> prevEvents ++ [timeEvent eventTime]
      Some (electorIsOwner, claimTag) -> prevEvents ++□
→[newElection]
    where
      newElection = EventData with
        t = eventTime
        election = Some (electorIsOwner, claimTag)
      version = newKey.version

```

This ensures that the next time the instrument is lifecycled, the current coupon is no longer included. This also works for other types of events, for example a barrier hit on a derivative instrument: if such an event is ever lifecycled it will persist on (a new version of) the instrument, ensuring that it will not be forgotten when the instrument is lifecycled in the future.

21.6.2.5 Including market observables

In our fixed rate bond example above, the coupon amount is pre-determined at the inception of the instrument. In contrast, a floating rate coupon is defined by the value of a reference rate during the lifetime of the bond. Since we do not know this value when the instrument is created, we need to define the coupon based on a future observation of the reference rate.

In the instrument definition, we need an identifier for the reference rate:

```
-- | This template models a floating rate bond.
-- It pays a floating coupon rate at the end of every coupon period.
-- This consists of a reference rate (observed at the beginning of the coupon
↳ period) plus a coupon
-- spread. For example, 3M Euribor + 0.5%.
template Instrument
  with
    depository : Party
      -- ^ The depository of the instrument.
    issuer : Party
      -- ^ The issuer of the instrument.
    id : Id
      -- ^ An identifier of the instrument.
    version : Text
      -- ^ The instrument's version.
    holdingStandard : HoldingStandard
      -- ^ The holding standard for holdings referencing this instrument.
    description : Text
      -- ^ A description of the instrument.
    floatingRate : FloatinRateTypes.FloatingRate
      -- ^ A description of the floating rate to be used. This supports both
↳ Libor and SOFR style
      -- reference rates (using a compounded index, e.g. the SOFR Index).
```

When we create the claims for the coupon payments, we can then use [ObserveAt](#) to refer to the value of the reference rate:

```
observedFloatingRate = ObserveAt fr.referenceRateId resetDate
```

In this example, the observable is a reference interest rate. Other instrument types can require other types of observables, such as an FX rate or a stock price.

21.6.2.6 Different ways to create and store the Contingent Claims tree

To summarize what we have seen so far, there are two different ways of using [Contingent Claims](#) in a Daml Finance instrument.

When using the [Generic Instrument](#), we create the claim tree at instrument inception and store this representation explicitly on the ledger. After a lifecycle event, for example a coupon payment, a new version of the instrument (with a different claim tree) supersedes the previous version.

In contrast, the approach used in this tutorial only stores the key economic terms of the bond on the ledger. The claim tree is not stored on-ledger, but it is created *on-the-fly* when needed (for example, when lifecycling).

Which approach is preferred?

The latter approach has the advantage that the claim tree can adapt to changes in reference data. A change to e.g. a holiday calendar would automatically impact the claim tree the next time it is dynamically created. This is not the case for the first approach, where the tree is static.

Also, if the economic terms of the instrument result in a very large claim tree, it could be desirable not to store it on the ledger for performance reasons.

Finally, the `dynamic` approach allows for the terms of the template to be very descriptive to anyone familiar with the payoff at hand.

On the other hand, if you need to quickly create a one-off instrument, the on-ledger approach allows you to create the claims directly from a script, without first having to define a dedicated template.

Also, if you need to explicitly access Contingent Claims representations of older versions of the instrument on the ledger, for example for auditing reasons, that would be achieved out of the box with the first approach.

21.6.3 Date Utility Functions: Calendar, Schedule, and Day Count

The Daml Finance library contains date-related utility functions for implementing industry-standard conventions. These functions are used internally in instruments like bonds and swaps, but they can also be helpful in your own custom use cases. For example, you can use these functions to:

- understand and validate the implementation of existing Daml Finance instruments
- compose existing Daml Finance instruments; for example, define a series of zero-coupon bonds according to a specific schedule of maturity dates
- develop your own instruments that depend on business day shifts, schedules, or day count conventions
- work with non-financial use cases

21.6.3.1 Calendar

The `Calendar` module contains various utility functions related to business days and date adjustments.

To distinguish business days and non-business days, set a holiday calendar. The `HolidayCalendarData` type defines the set of non-business days by specifying the days of the week that belong to the weekend, as well as the dates of designated holidays. The following example sets Saturday and Sunday as weekend days and specifies some additional holidays:

```
calendar = HolidayCalendarData with
  id = "USNY"
  weekend = [Saturday, Sunday]
  holidays = [date 2018 Jan 02, date 2018 Jan 31, date 2018 Feb 1]
```

To check whether a given date is a business day, use the `isBusinessDay` function:

```
isBusinessDay calendar (date 2018 Jan 02) == False
isBusinessDay calendar (date 2018 Jan 03) == True
```

You can also get the previous and next business day:

```
previousBusinessDay calendar (date 2018 Jan 03) === date 2018 Jan 01
```

```
nextBusinessDay calendar (date 2018 Jan 01) === date 2018 Jan 03
```

To find the date that corresponds to a specific number of business days in the future, use `addBusinessDays`:

```
addBusinessDays calendar 5 (date 2018 Jan 01) === date 2018 Jan 09
```

You can also get the date that corresponds to a number of business days in the past, by passing in a negative offset:

```
addBusinessDays calendar (-5) (date 2018 Feb 05) === date 2018 Jan 25
```

You can adjust a date according to a business day convention:

```
adjustDate calendar NoAdjustment (date 2018 Mar 31) === (date 2018 Mar 31)
adjustDate calendar Following (date 2018 Mar 31) === (date 2018 Apr 02)
adjustDate calendar ModifiedFollowing (date 2018 Mar 31) === (date 2018 Mar 30)
adjustDate calendar Preceding (date 2018 Apr 01) === (date 2018 Mar 30)
adjustDate calendar ModifiedPreceding (date 2018 Apr 01) === (date 2018 Apr 02)
```

For the full list of available conventions, see the [BusinessDayConventionEnum](#) reference. Use them to specify how non-business days are adjusted, including when the next or previous business day is around the end of the month.

21.6.3.2 RollConvention

The [RollConvention](#) module provides utility functions to add a period to a given date.

For example, you can add a day, week, month, or year to a date:

```
addPeriod (D.date 2018 Oct 01) (Period with periodMultiplier = 1; period = D) □
↳===
D.date 2018 Oct 02
addPeriod (D.date 2018 Oct 01) (Period with periodMultiplier = 1; period = W) □
↳===
D.date 2018 Oct 08
addPeriod (D.date 2018 Oct 01) (Period with periodMultiplier = 1; period = M) □
↳===
D.date 2018 Nov 01
addPeriod (D.date 2018 Oct 01) (Period with periodMultiplier = 1; period = Y) □
↳===
D.date 2019 Oct 01
```

This function can also handle edge cases. For example, when you add a period of one month to a date, the function makes adjustments if the resulting month has fewer days than the starting month:

```
addPeriod (D.date 2018 Oct 31) (Period with periodMultiplier = 1; period = M) □
↳===
D.date 2018 Nov 30
```

To subtract a period of time, use a negative offset:

```

addPeriod (D.date 2018 Nov 30) (Period with periodMultiplier = -1; period = M)
↳===
D.date 2018 Oct 30
addPeriod (D.date 2018 Jan 30) (Period with periodMultiplier = -1; period = M)
↳===
D.date 2017 Dec 30

```

You might need to find the start date of the next period according to a specific market convention, as described in the [RollConventionEnum](#) reference. The *Roll* convention specifies when the date is rolled.

For example, you can define an end-of-month roll:

```

next (D.date 2018 Oct 31) (Period with periodMultiplier = 1; period = M) EOM ===
D.date 2018 Nov 30

```

You can also set the roll to a specific day of the month:

```

next (D.date 2018 Oct 01) (Period with periodMultiplier = 1; period = M) (DOM
↳1) ===
D.date 2018 Nov 01

```

If the resulting month does not have enough days, the last day of the month is used instead:

```

next (D.date 2018 Oct 31) (Period with periodMultiplier = 1; period = M) (DOM
↳31) ===
D.date 2018 Nov 30

```

This function also takes leap days into account:

```

next (D.date 2019 Aug 31) (Period with periodMultiplier = 6; period = M) (DOM
↳31) ===
D.date 2020 Feb 29

```

The following example shows you how to roll to the *previous* period:

```

previous (D.date 2020 Feb 29) (Period with periodMultiplier = 6; period = M)
↳(DOM 31) ===
D.date 2019 Aug 31

```

The [RollConvention](#) functions are often used in the context of rolling out a schedule, as explained in the next section.

21.6.3.3 Schedule

The [Schedule](#) module contains functions for creating a series of time periods. A schedule can be used to represent different aspects of a financial instrument, for example:

- payment periods, which define when a bond coupon or a swap payment should be paid
- calculation periods, which define how the interest amount is calculated

The following example defines a periodic 3M (3-month) schedule that rolls on the 30th of the month:

```

periodicSchedule = PeriodicSchedule with
  businessDayAdjustment =
    BusinessDayAdjustment with calendarIds = ["USNY"]; convention =
↳ModifiedFollowing

```

(continues on next page)

(continued from previous page)

```

effectiveDateBusinessDayAdjustment = None
terminationDateBusinessDayAdjustment = None
frequency = Periodic Frequency with
  rollConvention = DOM 30; period = Period with period = M;
periodMultiplier = 3
effectiveDate = D.date 2018 Nov 30
firstRegularPeriodStartDate = None
lastRegularPeriodEndDate = None
stubPeriodType = None
terminationDate = D.date 2019 Nov 30

```

Because there is one year between the start date and the end date, this periodic schedule should correspond to four periods of 3M each:

```

expectedResult =
[ SchedulePeriod with
  unadjustedStartDate = D.date 2018 Nov 30
  unadjustedEndDate = D.date 2019 Feb 28
  adjustedStartDate = D.date 2018 Nov 30
  adjustedEndDate = D.date 2019 Feb 28
  stubType = None
, SchedulePeriod with
  unadjustedStartDate = D.date 2019 Feb 28
  unadjustedEndDate = D.date 2019 May 30
  adjustedStartDate = D.date 2019 Feb 28
  adjustedEndDate = D.date 2019 May 30
  stubType = None
, SchedulePeriod with
  unadjustedStartDate = D.date 2019 May 30
  unadjustedEndDate = D.date 2019 Aug 30
  adjustedStartDate = D.date 2019 May 30
  adjustedEndDate = D.date 2019 Aug 30
  stubType = None
, SchedulePeriod with
  unadjustedStartDate = D.date 2019 Aug 30
  unadjustedEndDate = D.date 2019 Nov 30
  adjustedStartDate = D.date 2019 Aug 30
  adjustedEndDate = D.date 2019 Nov 29
  stubType = None
]

```

Note the distinction between adjusted and unadjusted dates. The unadjusted date is the result of adding a specified time period to the start date of the previous schedule period. This date might fall on a non-business day. Apply a [BusinessDayAdjustment](#), to get an adjusted date that falls on a business day.

Now you can roll out the schedule to get the specific start and end date for each period, and compare the schedule to the expected result:

```
createSchedule calcs periodicSchedule === expectedResult
```

Schedules often use the concept of *stub periods*. The above schedule had only regular 3M periods. The following example reveals what happens if the schedule starts one month later:

```

periodicScheduleWithStub = PeriodicSchedule with
  businessDayAdjustment =
    BusinessDayAdjustment with calendarIds = ["USNY"]; convention = □
↳ ModifiedFollowing
  effectiveDateBusinessDayAdjustment = None
  terminationDateBusinessDayAdjustment = None
  frequency = Periodic Frequency with
    rollConvention = DOM 30; period = Period with period = M; □
↳ periodMultiplier = 3
  effectiveDate = D.date 2018 Dec 30
  firstRegularPeriodStartDate = Some $ D.date 2019 Feb 28
  lastRegularPeriodEndDate = None
  stubPeriodType = None
  terminationDate = D.date 2019 Nov 30

```

This schedule has only 11 months in it, which does not correspond to regular 3M periods (neither 3 nor 4 periods). To fix this, define a stub period. Using the preceding example, you could define a start date for the first regular period. (This implies a short initial stub period, in this case 2 months.) You would expect the following schedule:

```

expectedResultWithStub =
[ SchedulePeriod with
  unadjustedStartDate = D.date 2018 Dec 30
  unadjustedEndDate = D.date 2019 Feb 28
  adjustedStartDate = D.date 2018 Dec 31
  adjustedEndDate = D.date 2019 Feb 28
  stubType = Some ShortInitial
, SchedulePeriod with
  unadjustedStartDate = D.date 2019 Feb 28
  unadjustedEndDate = D.date 2019 May 30
  adjustedStartDate = D.date 2019 Feb 28
  adjustedEndDate = D.date 2019 May 30
  stubType = None
, SchedulePeriod with
  unadjustedStartDate = D.date 2019 May 30
  unadjustedEndDate = D.date 2019 Aug 30
  adjustedStartDate = D.date 2019 May 30
  adjustedEndDate = D.date 2019 Aug 30
  stubType = None
, SchedulePeriod with
  unadjustedStartDate = D.date 2019 Aug 30
  unadjustedEndDate = D.date 2019 Nov 30
  adjustedStartDate = D.date 2019 Aug 30
  adjustedEndDate = D.date 2019 Nov 29
  stubType = None
]

```

To configure different stub types, use the [StubPeriodTypeEnum](#) data type. You can configure whether the stub period should be at the beginning or end of the schedule, as well as whether the stub period should be longer or shorter than a regular period.

Roll out this schedule, which includes a stub period, and compare it to the expected result:

```
createSchedule calcs periodicScheduleWithStub === expectedResultWithStub
```

21.6.3.4 DayCount

Many instruments that pay interest (often expressed as an annualized rate) require an exact definition of how many days of interest belong to each payment period. The [DayCount](#) module provides functions to support such requirements. In particular, you can calculate a *day count fraction* (*dcf*) between two dates. This indicates the fraction of a full year between the dates.

For example, consider a one-year bond that pays a quarterly coupon according to a given schedule, like the one described in the previous section.

This bond does not have the same number of days in each period, which normally results in different coupon amounts for each period. Various market conventions address this and are provided in the [DayCountConventionEnum](#).

Consider the schedule with a short initial stub in the previous section. The following example uses the `Act360` day count convention:

```
calcDcf Act360 (D.date 2018 Dec 31) (D.date 2019 Feb 28) === 0.1638888889
```

This corresponds to the 2M short initial stub period. The day count fraction can be used to calculate a bond coupon or a swap payment for the given period, by multiplying it with the yearly interest rate of the instrument (such as 4% per annum).

You can compare this initial day count fraction with those of the second and third periods of this schedule, which are both regular (3M):

```
calcDcf Act360 (D.date 2019 Feb 28) (D.date 2019 May 30) === 0.2527777778
calcDcf Act360 (D.date 2019 May 30) (D.date 2019 Aug 30) === 0.2555555556
```

These day count fractions are clearly greater than the one of the first period, since they correspond to 3M instead of 2M. Note that they differ slightly: they do not contain the exact same number of days.

In addition to `Act360`, the [DayCountConventionEnum](#) supports several other day count conventions. You can compute some of them with `calcDcf`, using only a start and an end date as an input as shown above. Others, such as `ActActISDA`, are a bit more complicated because they require additional information. You can calculate them using the `calcPeriodDcf` function instead. This function takes a schedule period (containing stub information) as input, as well as the schedule end date and the payment frequency:

```
period = SchedulePeriod with
  unadjustedStartDate = D.date 1999 Nov 30
  unadjustedEndDate = D.date 2000 Apr 30
  adjustedStartDate = D.date 1999 Nov 30
  adjustedEndDate = D.date 2000 Apr 30
  stubType = Some LongFinal
maturityDate = D.date 2000 Apr 30
useAdjustedDatesForDcf = True
frequency = Periodic Frequency with
  rollConvention = EOM; period = Period with period = M; periodMultiplier = 3

calcPeriodDcf ActActISDA period useAdjustedDatesForDcf maturityDate frequency
↳ === 0.4155400854
```

21.6.3.5 Summary

You have learned about the date-related utility functions in the Daml Finance library. Here are some pointers regarding next steps, depending on what you want to do:

- understand and validate the implementation of existing Daml Finance instruments: the implementation of the Bond package could be a good starting point. It is explained and linked in the [How to leverage Contingent Claims in custom instrument implementations](#) tutorial.

- develop your own instruments that depend on business day shifts, schedules, or day count conventions: the [Payoff Modelling](#) tutorials describe the Contingent Claims framework step by step. You can then create the dates for your instruments using the functions described in this tutorial.

Chapter 22

Reference

This reference section contains code patterns, a glossary, as well as code-level documentation for each Daml Finance package.

22.1 Glossary

This page defines some of the terminology used in the Daml Finance library.

We strive to use descriptive names and stay as close as possible to the traditional financial meaning of familiar terms.

22.1.1 Account

An account contract is a relationship between two parties: a custodian (or account provider) and an owner.

An account is referenced by *holdings* and it is used to control who is entitled to instruct and receive holding transfers.

22.1.2 Instrument

An instrument describes the economic terms (rights and obligations) of one unit of a financial contract.

An instrument is referenced by *holdings*. It can be as simple as an ISIN code referencing real-world (off-ledger) security, or it can encode specific on-ledger lifecycling logic.

22.1.3 Holding

A holding contract represents the ownership of a certain amount of an [Instrument](#) by an owner at a custodian.

22.1.4 Fungibility

Fungibility refers to the ability of an [Instrument](#) to be interchanged with other individual instruments of the same type. Fungible holdings can be `split` and `merged`.

22.1.5 Transferability

Transferability refers to the ability to transfer ownership of units of an [Instrument](#) to a new owner at the same custodian.

22.1.6 Locking

Locking is a mechanism that adds a third-party authorization requirement to any interaction with a [Holding](#) (archive, transfer, split, merge, etc.).

It is used to ensure that holdings committed to a certain workflow are not consumed by other workflows.

22.1.7 Crediting / Debiting

Crediting is the process of creating new [Holdings](#) for a given instrument and debiting, conversely, is removing existing ones.

22.1.8 Disclosure

Disclosure is the ability to reveal a contract to a third party by adding them as an observer.

22.1.9 Settlement

Settlement is the (possibly simultaneous) execution of ownership transfers according to predefined instructions.

Many financial transactions are traditionally settled a few days after execution.

22.1.10 Lifecycling

Lifecycling refers to the evolution of [Instruments](#) over their lifetime.

Lifecycling can deal with intrinsic events, like contractual cash flows, and/or extrinsic events like corporate actions or elections.

22.1.11 Lifecycling effect

A Lifecycling effect refers to the output of [Lifecycling](#). Depending on the nature of the instrument being lifecycled, the effect(s) can be of different types:

- cash flow (e.g. a bond coupon)
- other distributions (e.g. shares resulting from a bonus issue)
- exchange of principal (e.g. the FX transaction resulting from a foreign exchange swap)
- exchange of other assets (e.g. shares vs cash resulting from a physically settled option)

22.2 Patterns

This page explains some common design patterns used in the Daml Finance library.

22.2.1 Factory pattern

Factories are helper contracts that are used to create instruments, holdings, and other contracts. The reason why using factories is a recommended pattern when using Daml Finance has to do with application decoupling / upgradeability of your application.

For example, suppose that you are writing Daml code to issue equity instruments. Your workflow references the version 0.2.1 of the [Equity implementation package](#) and at some point creates an instrument as follows.

```
create Equity.Instrument with
  issuer = myParty
  id = Id "MyCompany"
  ..
```

If the equity package gets updated to version 0.2.2 and a new field is added to the instrument (or a choice is changed, or a new lifecycle event is added,) then you are forced to upgrade your Daml code in order to use the new feature and will have to deal with upgrading multiple templates on the ledger.

A safer approach is for your Daml code to only reference the [Equity interface package](#), which contains interface definitions and is updated less frequently.

However, you would now need a way to create equity instruments without referencing `Daml.Finance.Instrument.Equity.V0` in your main Daml workflow. To do this, you can setup a Script to run during ledger initialisation that will create a [factory contract](#) and cast it to the corresponding [interface](#). You can then use the factory in your main workflow code to create the instruments.

When an upgraded instrument comes along, you would need to write code to archive the old factory and create the new one, in order to issue the new instruments. However, the Daml code for your workflow could in principle stay untouched.

For an example where the Factory pattern is used, check out the [Holdings tutorial](#).

22.2.2 Reference pattern

The Reference pattern is used to leverage the functionalities of [Contract Keys](#) when working with interfaces. This is required as there is currently no built-in support at the language level for interface keys.

We want for instance to use an [InstrumentKey](#) to identify instruments across a number of implementing templates.

To do that, we define a Reference template that

is keyed by the *InstrumentKey*

contains the interface contract id of the target instrument

You can then fetch an interface by key by

fetching the Reference template by key (`fetchByKey`)

reading and `fetch`-ing the stored contract id

Similarly, this pattern let you exercise a choice on an interface by key .

The Reference pattern is currently used in Daml Finance for instruments, accounts, and the holding factory. To maintain synchronization between a template and its corresponding *Reference*, we simultaneously create (archive) instances of both. Additionally, if the contract id of the target template changes, we update the *Reference* instance accordingly.

It is important to understand this pattern should you implement custom instruments, accounts or holding factories.

22.2.3 View of an interface contract and the *GetView* choice

There are different ways to access the data of a contract, for example the terms of an instrument:

1. `fetch` the interface contract using its contract ID (this requires the submitting party to be a stakeholder of the contract). It is then possible to use the `view` built-in method to get the interface view.
2. `GetView`: by calling this choice on the interface, for example on a [callable bond](#), a party can get the view of a contract, without necessarily being a stakeholder of the contract. This can be useful in situations where someone needs access to reference data, but should not be a stakeholder of the contract. Specifically, if *publicParty* is an observer of an *instrumentCid*, a party would only require *readAs* rights of *publicParty* in order to exercise `GetView`. In the Daml Finance library, this choice has been implemented not only for instruments but also for other types of contracts, e.g. [Holdings](#) and lifecycle related contracts like [Rule](#) and [Effect](#).

22.3 Daml Finance

Here is a complete list of modules in the financial library:

22.3.1 ContingentClaims.Core.V3.Builders

22.3.1.1 Functions

unrollDates : `Int -> Int -> [Month] -> Int -> [Date]`

Helper function to generate a series of fixing dates, e.g. for coupon payments in `fixed`. This assumes `fixingMonths` and `fixingDates` are ordered. The Daml Finance library(<https://github.com/digital-asset/daml-finance>) has more feature-complete date handling functions.

forward : `t -> Observation t x o -> Claim t x a o -> Claim t x a o`

Forward agreement. Discounted by (potentially stochastic) interest rate `r`.

fra : `t -> t -> Observation t x o -> Observation t x o -> Claim t x a o -> Claim t x a o`

Forward rate agreement.

zcb : `t -> x -> ccy -> Claim t x ccy o`

Zero Coupon Bond.

floating : `Observation t x o -> Observation t x o -> ccy -> [t] -> Claim t x ccy o`

A floating rate bond.

fixed : `x -> x -> ccy -> [t] -> Claim t x ccy o`

A (fixed rate) coupon paying bond.

european : `t -> Claim t x a o -> Claim t x a o`

European option on the input claim. At maturity, the holder must EXERCISE or EXPIRE the claim. e.g. call option on S&P 500:

```
european (date 2021 05 14) (observe "SPX" - pure 4200)
```

bermudan : `[t] -> Claim t x a o -> Claim t x a o`

Bermudan option on the input claim. Given a pre-defined set of times $\{t_1, t_2, \dots, t_N\}$, it allows the holder to acquire the underlying claim on at most one of these times. At each election time before maturity, the holder must EXERCISE the option or POSTPONE. At maturity, the holder must EXERCISE or EXPIRE.

american : `t -> t -> Claim t x a o -> Claim t x a o`

American option (knock-in). The lead parameter is the first possible acquisition date.

swap : `([t] -> Claim t x a o) -> ([t] -> Claim t x a o) -> [t] -> Claim t x a o`

Asset swap on specific fixing dates `[t]`. For example:

```
fixedUsdVsFloatingEur : [t] -> Serializable.Claim Text
fixedUsdVsFloatingEur =
  fixed 100.0 0.02 "USD" `swap` floating (observe "USDEUR" * pure 100.0)
  ↪ (observe "EUR1M") "EUR"
```

22.3.2 ContingentClaims.Core.V3.Claim

22.3.2.1 Functions

zero : [Claim](#) t x a o

Constructs a claim without rights or obligations.

one : a -> [Claim](#) t x a o

Constructs a claim that delivers one unit of a immediately to the bearer.

give : [Claim](#) t x a o -> [Claim](#) t x a o

Constructs a claim that reverses the obligations of the bearer and their counterparty.

and : [Claim](#) t x a o -> [Claim](#) t x a o -> [Claim](#) t x a o

Used to additively combine two claims together. In order to use this, you must import this module qualified or hide the `and` operator from `Prelude`.

or : [Electable](#) t x a o -> [Electable](#) t x a o -> [Claim](#) t x a o

Gives the bearer the right to choose between the input claims. In order to use this, you must import this module qualified or hide the `or` operator from `Prelude`.

andList : [[Claim](#) t x a o] -> [Claim](#) t x a o

Used to additively combine a list of claims together. It is equivalent to applying the `and` builder recursively.

orList : [[Electable](#) t x a o] -> [Claim](#) t x a o

Gives the bearer the right to choose between the input claims. It is equivalent to applying the `or` builder recursively.

cond : [Inequality](#) t x o -> [Claim](#) t x a o -> [Claim](#) t x a o -> [Claim](#) t x a o

Gives the bearer the right to the first claim if predicate is true, else the second claim.

scale : [Observation](#) t x o -> [Claim](#) t x a o -> [Claim](#) t x a o

Multiplies the input claim by a scaling factor (which can be non-deterministic).

when : [Inequality](#) t x o -> [Claim](#) t x a o -> [Claim](#) t x a o

Acquires the input claim on the *first instant* that `predicate` is true.

anytime : [Inequality](#) t x o -> [Text](#) -> [Claim](#) t x a o -> [Claim](#) t x a o

Gives the bearer the right to enter a claim at any time `predicate` is true.

until : [Inequality](#) t x o -> [Claim](#) t x a o -> [Claim](#) t x a o

Expires the input claim on the *first instant* that `predicate` is true.

mapParams : (t -> i) -> (i -> t) -> (a -> a') -> (o -> o') -> (x -> x') -> [Claim](#) i x a o -> [Claim](#) t x' a' o'

Replaces parameters in a claims using the input mapping functions. This can be used to e.g. map the time parameter in a claim from `Date` to `Time`, or to map the asset type parameter from an abstract `Text` to a concrete `InstrumentKey`.

at : t -> [Inequality](#) t x o

Given `t`, constructs a predicate that is `True` for time `t`, `False` otherwise.

upTo : t -> [Inequality](#) t x a

Given `t`, constructs a predicate that is `True` for time `t`, `False` otherwise.

(<=) : [Observation](#) t x o -> [Observation](#) t x o -> [Inequality](#) t x o

Given observations `o1` and `o2`, constructs the predicate `o1 ≤ o2`. In order to use this, you must import this module qualified or hide the `(<=)` operator from `Prelude`.

compare : (Ord t, Ord x, Number x, Divisible x, CanAbort m) => (o -> t -> m x) -> Inequality t x o -> t -> m Bool

Reify the `Inequality` into an observation function. This function is used to convert an abstract predicate, e.g. $S \leq 50.0$ to the actual boolean observation function `t -> m Bool`.

22.3.3 ContingentClaims.Core.V3.Internal.Claim

22.3.3.1 Data Types

data `Claim` t x a o

Core data type used to model cashflows of instruments. In the reference paper from Peyton-Jones this is called ‘Contract’. We renamed it to avoid ambiguity.

t corresponds to the time parameter.

x corresponds to the `Observation` output type. An observation is a function from t to x. A common choice is to use `Time` and `Decimal`, respectively.

a is the representation of a deliverable asset, e.g. a `Text` ISIN code or an `InstrumentKey`.

o is the representation of an observable, e.g. a `Text`.

You should build the `Claim` using the smart constructors (e.g. `zero`, `and`) instead of using the data constructors directly (`Zero`, `And`).

Zero

Represents an absence of claims. Monoid `And` identity.

One a

The bearer acquires one unit of a *immediately*.

Give (`Claim` t x a o)

The obligations of the bearer and the counterparty are reversed.

And

Used to combine multiple rights together.

Field	Type	Description
a1	<code>Claim</code> t x a o	
a2	<code>Claim</code> t x a o	
as	<code>[Claim</code> t x a o]	

Or

Gives the bearer the right to choose between several claims.

Field	Type	Description
or1	Electable t x a o	
or2	Electable t x a o	
ors	[Electable t x a o]	

Cond

Gives the bearer the right to the first claim if `predicate` is true, else the second claim.

Field	Type	Description
predicate	Inequality t x o	
success	Claim t x a o	
failure	Claim t x a o	

Scale

Multiplies the `claim` by `k` (which can be non-deterministic).

Field	Type	Description
k	Observation t x o	
claim	Claim t x a o	

When

Defers the acquisition of `claim` until *the first instant* that `predicate` is true.

Field	Type	Description
predicate	Inequality t x o	
claim	Claim t x a o	

Anytime

Gives the bearer the right to enter a claim at any time the predicate is true.

Field	Type	Description
predicate	Inequality t x o	
electable	Electable t x a o	

Until

Expires said claim on the *first instant* that `predicate` is true.

Field	Type	Description
predicate	Inequality t x o	
claim	Claim t x a o	

instance Corecursive ([Claim](#) t x a o) (ClaimF t x a o)

instance Recursive ([Claim](#) t x a o) (ClaimF t x a o)

instance (Eq a, Eq x, Eq o, Eq t) => Eq ([Claim](#) t x a o)

instance (Show t, Show x, Show a, Show o) => Show ([Claim](#) t x a o)

instance Monoid ([Claim](#) t x a o)

instance Semigroup ([Claim](#) t x a o)

type [Electable](#) t x a o = (Text, [Claim](#) t x a o)

Type synonym for sub-trees that can be elected in an `Or` or `Anytime` node. The textual tag is used to identify each sub-tree when an election is made.

data [Inequality](#) t x o

Data type for boolean predicates supported by the library. A boolean predicate is a generic function with signature `t -> Bool`. However, a limited set of predicates is currently supported.

[TimeGte](#) t

True when `time ≥ t`, False otherwise.

[TimeLte](#) t

True when `time ≤ t`, False otherwise.

[Lte](#) ([Observation](#) t x o, [Observation](#) t x o)

True when `o(t) ≤ o'(t)`, False otherwise, for a pair of observations `o, o'`.

instance (Eq t, Eq x, Eq o) => Eq ([Inequality](#) t x o)

instance (Show t, Show x, Show o) => Show ([Inequality](#) t x o)

22.3.4 ContingentClaims.Core.V3.Observation

22.3.4.1 Data Types

data [Observation](#) t x o

Implementation of market observables. Conceptually it is helpful to think of this as the type `t -> x`, or `t -> Update x`.

[Const](#)

A numerical constant, e.g. `10.0`.

Field	Type	Description
value	x	

Observe

A named parameter, e.g. "LIBOR 3M".

Field	Type	Description
key	o	

ObserveAt

A named parameter, e.g. "LIBOR 3M", observed at an explicit point in time.

Field	Type	Description
key	o	
t	t	

Add (*Observation* t x o, *Observation* t x o)

Sum of two observations.

Neg (*Observation* t x o)

Opposite of an observation.

Mul (*Observation* t x o, *Observation* t x o)

Product of two observations.

Div (*Observation* t x o, *Observation* t x o)

Division of two observations.

instance Corecursive (*Observation* t x o) (ObservationF t x o)

instance Recursive (*Observation* t x o) (ObservationF t x o)

instance Functor (*Observation* t x)

instance (Eq x, Eq o, Eq t) => Eq (*Observation* t x o)

instance Additive x => Additive (*Observation* t x o)

instance Multiplicative x => Divisible (*Observation* t x o)

instance Multiplicative x => Multiplicative (*Observation* t x o)

instance (Additive x, Multiplicative x) => Number (*Observation* t x o)

instance (Show t, Show x, Show o) => Show (*Observation* t x o)

22.3.4.2 Functions

pure : x -> *Observation* t x o

Smart constructor for Const. Lifts a constant to an observation.

observe : o -> *Observation* t x o

Smart constructor for Observe. Looks up the value of o.

eval : (Ord t, Number x, Divisible x, CanAbort m) => (o -> t -> m x) -> *Observation* t x o -> t -> m x

Reify the *Observation* into an observation function. This function is used to convert an abstract observation, e.g. LIBOR 3M + 0.005 to the actual observation function t -> m x.

mapParams : (i -> t) -> (o -> o') -> (x -> x') -> *Observation* i x o -> *Observation* t x' o'

The functor map operation and also map any parameters to keys. For example, could map the param "spot" to an ISIN code "GB123456789". Also contra-maps time parameter, i.e. from relative time values to absolute ones.

@ mapParams identity = bimap

22.3.5 ContingentClaims.Core.V3.Util.Recursion

This module collects a set of utilities used to execute recursion schemes. The morphisms ending in 'M' are monadic variants, allowing to interleave, e.g., *Update* or *Script*. *cataM* after Tim Williams' talk, <https://www.youtube.com/watch?v=Zw9KeP3OzpU>.

22.3.5.1 Functions

paraM : (Monad m, *Traversable* f, Recursive b f) => (f (b, a) -> m a) -> b -> m a
Monadic paramorphism.

anaM : (Monad m, *Traversable* f, Corecursive b f) => (a -> m (f a)) -> a -> m b
Monadic anamorphism.

apoM : (Monad m, *Traversable* f, Corecursive b f) => (a -> m (f (*Either* b a))) -> a -> m b
Monadic apomorphism.

futuM : (Monad m, *Traversable* f, Corecursive b f) => (a -> m (f (Free f a))) -> a -> m b
Monadic futuorphism.

apoCataM : (Monad m, *Traversable* f, Corecursive b f) => (f b -> b) -> (a -> m (f (*Either* b a))) -> a -> m b
Monadic lazy unfold (apoM) followed by a fold (cata). This Specialised lazy re-fold is used by *lifecycle*.

hylaM : (*Traversable* f, Monad n) => (f b -> b) -> (a -> n (f a)) -> a -> n b
A modified *hyla* (refold), with an interleaved monad effect (typically *Update*).

ghylaM : (Comonad w, *Traversable* f, Monad m, *Traversable* m, Monad n) => (f (w c) -> w (f c)) -> (m (f d) -> f (m d)) -> (f (w b) -> b) -> (a -> n (f (m a))) -> a -> n b
Generalised hylomorphism (with monadic unfold).

funzip : *Functor* f => f (a, b) -> (f a, f b)
Functor unzip.

synthesize : (*Functor* f, Recursive b f) => (f attr -> attr) -> b -> Cofree f attr
Annotate a recursive type bottom-up.

inherit : (*Functor* f, Corecursive b f, Recursive b f) => (b -> attr -> attr) -> attr -> b -> Cofree f attr
Annotate a recursive type top-down.

22.3.6 ContingentClaims.Lifecycle.V3.Lifecycle

22.3.6.1 Data Types

data *Pending* t a

Used to specify pending payments.

Pending

Field	Type	Description
t	t	Payment time.
amount	<i>Decimal</i>	Amount of asset to be paid.
asset	a	Asset in which the payment is denominated.

instance (Eq t, Eq a) => Eq (*Pending* t a)

instance (Show t, Show a) => Show (*Pending* t a)

data *Result* t a o

Returned from a `lifecycle` operation.

Result

Field	Type	Description
pending	[<i>Pending</i> t a]	Payments requiring settlement.
remaining	C t a o	The tree after lifecycled branches have been pruned.

instance (Eq a, Eq o, Eq t) => Eq (*Result* t a o)

instance (Show t, Show a, Show o) => Show (*Result* t a o)

22.3.6.2 Functions

lifecycle : (Ord t, Eq a, CanAbort m) => (o -> t -> m *Decimal*) -> C t a o -> t -> t -> m (*Result* t a o)

Collect claims falling due into a list, and return the tree with those nodes pruned. `m` will typically be `Update`. It is parametrised so it can be run in a `Script`. The first argument is used to lookup the value of any `Observables`. Returns the pruned tree + pending settlements up to the provided market time.

exercise : (Ord t, Eq a, Eq o, CanAbort m) => (o -> t -> m *Decimal*) -> (Bool, Text) -> C t a o -> t -> t -> m (C t a o)

Acquire `Anytime` and `Or` nodes, by making an election. Import this qualified to avoid clashes with `Prelude.exercise`.

22.3.7 ContingentClaims.Lifecycle.V3.Util

This module defines a set of utility functions to extract information from claim trees.

22.3.7.1 Functions

fixings : *Claim* t x a o -> [t]

Return the fixing dates of a claim. This does not discriminate between optional dates which may result from a condition, and outright fixings. It also does not correctly account for malformed trees, where subtrees are orphaned due to impossible *When* statements, e.g., *When* (t > 1) ((*When* t < 1) _).

expiry : *Ord* t => *Claim* t x a o -> *Optional* t

Return the time after which the claim is worthless, i.e., value = 0, if such a time exists. Also known as ‘maturity’ or ‘horizon’ in the Eber/Jones paper.

payoffs : (*Eq* t, *Eq* x, *Eq* o, *Multiplicative* x) => *Claim* t x a o -> [(*Observation* t x o, a)]

Return a list of possible scale-factor/payoff pairs. This does not discriminate between conditional and outright payoffs.

pruneZeros : *Claim* t x a o -> *Claim* t x a o

Prunes sub-trees which are *Zero*.

isZero : *Claim* t x a o -> *Bool*

Checks if a claim is the *Zero* claim. This avoids requiring the equality type constraint on a.

22.3.8 ContingentClaims.Valuation.V0.MathML

22.3.8.1 Typeclasses

class *ToXml* a **where**

Renders an *Expr* into MathML presentation format.

presentation : a -> *Xml*

instance *ToXml* t => *ToXml* (*Expr* t)

instance *ToXml* *Decimal*

instance *ToXml* *Text*

instance *ToXml* *Date*

22.3.9 ContingentClaims.Valuation.V0.Stochastic

22.3.9.1 Typeclasses

class *IsIdentifier* t **where**

localVar : *Int* -> t

Produce a local identifier of type t, subindexed by i.

22.3.9.2 Data Types

data *Expr* t

Represents an expression of t-adapted stochastic processes.

Const *Decimal*

Ident t

Proc

Field	Type	Description
name	<i>Text</i>	
process	<i>Process</i> t	
filtration	t	

Sup

Field	Type	Description
lowerBound	t	
tau	t	
rv	<i>Expr</i> t	

Sum [*Expr* t]

Neg (*Expr* t)

Mul (*Expr* t, *Expr* t)

Pow (*Expr* t, *Expr* t)

I (*Expr* t, *Expr* t)

E

Field	Type	Description
rv	<i>Expr</i> t	
filtration	t	

instance *ToXml* t => *ToXml* (*Expr* t)

instance *Corecursive* (*Expr* t) (*ExprF* t)

instance *Recursive* (*Expr* t) (*ExprF* t)

instance *Eq* t => *Eq* (*Expr* t)

instance *Show* t => *Show* (*Expr* t)

data *ExprF* t x

Base functor for *Expr*. Note that this is ADT is re-used in a couple of places, e.g., *Process*, where however not every choice is legal and will lead to a partial evaluator.

ConstF Decimal*IdentF* t*ProcF*

Field	Type	Description
name	Text	
process	Process t	
filtration	t	

SupF

Field	Type	Description
lowerBound	t	
tau	t	
rv	x	

SumF [x]*NegF* x*MulF*

Field	Type	Description
lhs	x	
rhs	x	

PowF

Field	Type	Description
lhs	x	
rhs	x	

I_F

Field	Type	Description
lhs	x

E_F

Field	Type	Description
rv	x	
filtration	t	

instance Corecursive (*Expr* t) (*ExprF* t)

instance Recursive (*Expr* t) (*ExprF* t)

instance Functor (*ExprF* t)

instance Foldable (*ExprF* t)

instance Traversable (*ExprF* t)

data *Process* t

A stochastic processes. Currently this represents a Geometric Brownian Motion, i.e., $dX/X = \mu dt + \sigma dW$. Eventually, we wish to support other processes such as Levy.

Process

Field	Type	Description
dt	<i>Expr</i> t	
dW	<i>Expr</i> t	

instance *Eq* t => *Eq* (*Process* t)

instance *Show* t => *Show* (*Process* t)

22.3.9.3 Functions

riskless : t -> *Process* t

Helper function to create a riskless process $dS = r dt$.

gbm : t -> t -> *Process* t

Helper function to create a geometric BM $dS = \mu dt + \sigma dW$.

fapf : (*Eq* a, *Show* a, *Show* o, *IsIdentifier* t) => a -> (a -> *Process* t) -> (a -> a -> *Process* t) -> (o -> *Process* t) -> t -> *Claim* t *Decimal* a o -> *Expr* t

Converts a *Claim* into the Fundamental Asset Pricing Formula. The expressions are defined as E1-E10 in the Eber/Peyton-Jones paper. This is still an experimental feature.

simplify : *Expr* t -> *Expr* t

This is meant to be a function that algebraically simplifies the FAPF by

1. using simple identities and ring laws
2. change of numeraire technique. This is still an experimental feature.

22.3.10 Daml.Finance.Account.V4.Account

22.3.10.1 Templates

template *Account*

A relationship between a custodian and an asset owner. It is referenced by holdings.

Signatory: custodian, owner, Lockable.getLockers this

Field	Type	Description
custodian	Party	The account provider.
owner	Party	The account owner.
lock	Optional Lock	An optional lock for the account.
controllers	Controllers	Controllers of transfers.
id	Id	Identifier of the account.
description	Text	Description of the account.
holdingFactory	HoldingFactoryKey	Associated holding factory.
observers	PartiesMap	Observers.

Choice Archive

Controller: custodian, owner, Lockable.getLockers this

Returns: ()

(no fields)

interface instance *I* for [Account](#)**interface instance** *I* for [Account](#)**interface instance** *I* for [Account](#)**template** [Factory](#)

Template used to create accounts.

Signatory: provider

Field	Type	Description
provider	Party	The factory's provider.
observers	PartiesMap	The factory's observers.

Choice Archive

Controller: provider

Returns: ()

(no fields)

interface instance *I* for [Factory](#)**interface instance** *I* for [Factory](#)

22.3.10.2 Data Types

type *T* = [Account](#)Type synonym for [Account](#).

22.3.11 Daml.Finance.Claims.V3.Lifecycle.Rule

22.3.11.1 Templates

template [Rule](#)

Rule to process an event for instruments that are modelled using "on-the-fly" claims (the tree is not stored on-ledger but generated dynamically). This rule supports both time update events and election events.

Signatory: providers

Field	Type	Description
providers	Parties	Providers of the lifecycling rule.
lifecyclel	Party	Party performing the lifecycling.
observers	PartiesMap	Observers of the rule.
id	Id	Identifier for the rule contract.
description	Text	Textual description.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance [Exercisable](#) for [Rule](#)

interface instance [I](#) for [Rule](#)

interface instance [I](#) for [Rule](#)

22.3.12 [Daml.Finance.Claims.V3.Util](#)

22.3.12.1 Functions

[isZero](#) : [Party](#) -> [I](#) -> [Update Bool](#)

Checks if all input claims are zero.

[isZero'](#) : [[TaggedClaim](#)] -> [Bool](#)

Checks if all input claims are zero.

[toTime](#) : (t -> [Time](#)) -> [Claim](#) t x a o -> [Claim Time](#) x a o

Maps the time parameter in a [Claim](#) to [Time](#). As [Time](#) is generally understood to express UTC time, we recommend mapping to UTC time.

22.3.13 [Daml.Finance.Claims.V3.Util.Builders](#)

This module includes utility functions used to build contingent claim trees that represent specific payoffs. A [Schedule](#) is usually used as an input to these utility functions. Given that schedules are defined in terms of dates, a claim where the time parameter is [Date](#) is returned. These are then mapped to claims where the time parameter is [Time](#) using a (user-provided) conversion function.

22.3.13.1 Data Types

type [C](#) = [Claim](#) [Date](#) [Decimal](#) [Deliverable](#) [Observable](#)

type [FixingDates](#) = [DateOffset](#)

type [O](#) = [Observation](#) [Date](#) [Decimal](#) [Observable](#)

22.3.13.2 Functions

prepareAndTagClaims : (Date -> Time) -> [C] -> Text -> TaggedClaim

Convert the claims to UTCTime and tag them.

createFixRatePaymentClaimsList : Schedule -> PeriodicSchedule -> Bool -> Decimal -> Bool -> DayCountConventionEnum -> Decimal -> Deliverable -> [C]

createFixRatePaymentClaims : (Date -> Time) -> Schedule -> PeriodicSchedule -> Bool -> Decimal -> Bool -> DayCountConventionEnum -> Decimal -> Deliverable -> TaggedClaim

Calculate a fix rate amount for each payment date and create claims.

createRatePaymentClaims : (Date -> Time) -> Schedule -> PeriodicSchedule -> Bool -> Decimal -> Bool -> DayCountConventionEnum -> Decimal -> Deliverable -> Optional FloatingRate -> HolidayCalendarData -> TaggedClaim

Calculate a floating rate amount for each payment date and create claims. This is a general function that supports both LIBOR and SOFR-COMPOUND reference rates. It also supports a fix rate spread. If no floating rate is provided, only the fix spread is used, i.e. fix rate claims are created.

createConditionalCreditFixRatePaymentClaims : (Date -> Time) -> Schedule -> PeriodicSchedule -> Bool -> Decimal -> Bool -> DayCountConventionEnum -> Decimal -> Deliverable -> Observable -> TaggedClaim

Calculate a fix rate amount (if a credit event has not yet happened) for each payment date and create claims.

createCreditEventPaymentClaims : (Date -> Time) -> Bool -> Decimal -> Deliverable -> Observable -> Observable -> PeriodicSchedule -> TaggedClaim

Calculate a (1-recoveryRate) payment if a credit event just happened and create claims.

createAssetPerformancePaymentClaims : (Date -> Time) -> Schedule -> PeriodicSchedule -> Bool -> Bool -> DayCountConventionEnum -> Decimal -> Deliverable -> [(Text, Decimal)] -> TaggedClaim

Calculate the asset performance for each payment date and create claims. The performance is calculated using the weighted performance of the basket underlyings from the start date to the end date of each payment period. The reference asset Observables need to contain the appropriate type of fixings:

- unadjusted fixings in case of a price return asset swap
- adjusted fixings in case of a total return asset swap

createFxAdjustedPrincipalClaim : (Date -> Time) -> Bool -> Decimal -> Decimal -> Deliverable -> Date -> TaggedClaim

Create an FX adjusted principal claim. This can be used for both FX swaps (using the appropriate FX rate) and single currency bonds (setting the FX rate to 1.0).

createVanillaOptionClaim : (Date -> Time) -> Decimal -> Observable -> Deliverable -> Date -> Bool -> Optional Decimal -> Decimal -> C

Create the claim for a long vanilla option (cash-settled, automatically exercised).

createEuropeanCashClaim : (Date -> Time) -> Bool -> Decimal -> Observable -> Deliverable -> Date -> Bool -> Optional Decimal -> Decimal -> TaggedClaim

Create the claim for a cash-settled, automatically exercised option (long or short).

createBarrierEuropeanCashClaim : (Date -> Time) -> Bool -> Decimal -> Observable -> Deliverable -> Date -> Bool -> Decimal -> Date -> Bool -> Bool -> Optional Decimal -> Decimal -> TaggedClaim

Create the claim for a barrier option (automatically exercised, cash-settled).

createEuropeanPhysicalClaim : (Date -> Time) -> Bool -> Decimal -> Deliverable -> Deliverable -> Date -> Bool -> TaggedClaim

Create the claim for a physically settled European option.

createDividendOptionClaim : (Date -> Time) -> Date -> InstrumentQuantity -> Optional InstrumentQuantity -> Optional InstrumentQuantity -> TaggedClaim

Create the claim for a physically settled Dividend option.

22.3.14 Daml.Finance.Claims.V3.Util.Date

22.3.14.1 Data Types

type O = Observation Date Decimal Observable

22.3.14.2 Functions

convertImplicitDcfToActualDcf : O -> SchedulePeriod -> Bool -> PeriodicSchedule -> DayCountConventionEnum -> O

Calculate a conversion factor if the dcf used for a floating rate compounded index does not match the dcf used for an instrument.

22.3.15 Daml.Finance.Claims.V3.Util.Lifecycle

22.3.15.1 Functions

timeEvent : Time -> EventData

Constructor for a time event.

electionEvent : Time -> Bool -> Text -> EventData

Constructor for an election event.

lifecycleClaims : [ContractId I] -> Time -> [TaggedClaim] -> [EventData] -> Update ([TaggedClaim], [Pending])

Lifecycle a set of claims at specified events.

netOnTag : [Pending] -> [Pending]

Net pending payments on the same instrument, which also have the same tag.

lifecycle : Party -> [ContractId I] -> I -> [EventData] -> Update ([TaggedClaim], [Pending])

Lifecycle a claim instrument at specified events.

splitPending : [Pending] -> ([InstrumentQuantity], [InstrumentQuantity])

Map pending settlements into corresponding instrument quantities and split them into consumed and produced. Pending items with an amount of 0.0 are discarded.

22.3.16 Daml.Finance.Data.V4.Numeric.Observation

22.3.16.1 Templates

template *Factory*

Implementation of the corresponding Observation Factory.

Signatory: provider

Field	Type	Description
provider	Party	The factory's provider.
observers	PartiesMap	The factory's observers.

Choice Archive

Controller: provider

Returns: ()

(no fields)

interface instance *I* for [Factory](#)

interface instance *I* for [Factory](#)

template *Observation*

An implementation of `NumericObservable` that explicitly stores time-dependent numerical values. For example, it can be used for equity or rate fixings.

Signatory: provider

Field	Type	Description
provider	Party	The reference data provider.
id	<i>Id</i>	A textual identifier.
observations	Map Time Decimal	The time-dependent values.
observers	PartiesMap	Observers.

Choice Archive

Controller: provider

Returns: ()

(no fields)

interface instance *I* for [Observation](#)

interface instance *I* for [Observation](#)

interface instance *I* for [Observation](#)

22.3.16.2 Data Types

type *T* = [Observation](#)

Type synonym for `Observation`.

22.3.17 Daml.Finance.Data.V4.Reference.HolidayCalendar

22.3.17.1 Templates

template [Factory](#)

Implementation of the corresponding HolidayCalendar Factory.

Signatory: provider

Field	Type	Description
provider	Party	The factory's provider.
observers	PartiesMap	The factory's observers.

Choice Archive

Controller: provider

Returns: ()

(no fields)

interface instance *I* for [Factory](#)

interface instance *I* for [Factory](#)

template [HolidayCalendar](#)

Holiday calendar of an entity (typically an exchange or a currency). It is maintained by a reference data provider.

Signatory: provider

Field	Type	Description
calendar	HolidayCalendarData	Holiday Calendar Data used to define holidays.
observers	PartiesMap	Observers.
provider	Party	The party maintaining the HolidayCalendar.

Choice Archive

Controller: provider

Returns: ()

(no fields)

Choice [GetCalendar](#)

Returns the calendar's HolidayCalendarData.

Controller: viewer

Returns: [HolidayCalendarData](#)

Field	Type	Description
viewer	Party	The party fetching the calendar.

interface instance *I* for [HolidayCalendar](#)

interface instance *I* for [HolidayCalendar](#)

22.3.17.2 Data Types

data *HolidayCalendarKey*

Key used to look up the holiday calendar of an entity, as defined by a reference data provider.

HolidayCalendarKey

Field	Type	Description
provider	<i>Party</i>	The party maintaining the HolidayCalendar.
id	<i>Text</i>	A textual label identifying the calendar (e.g. "NYSE" for the New York Stock Exchange holiday calendar).

instance *Eq HolidayCalendarKey*

instance *Show HolidayCalendarKey*

instance *HasExerciseByKey HolidayCalendar HolidayCalendarKey GetCalendar HolidayCalendarData*

instance *HasExerciseByKey HolidayCalendar HolidayCalendarKey Archive ()*

instance *HasFetchByKey HolidayCalendar HolidayCalendarKey*

instance *HasFromAnyContractKey HolidayCalendar HolidayCalendarKey*

instance *HasKey HolidayCalendar HolidayCalendarKey*

instance *HasLookupByKey HolidayCalendar HolidayCalendarKey*

instance *HasMaintainer HolidayCalendar HolidayCalendarKey*

instance *HasToAnyContractKey HolidayCalendar HolidayCalendarKey*

22.3.17.3 Functions

getHolidayCalendars : *Party -> Party -> [Text] -> Update [HolidayCalendarData]*

Retrieve holiday calendar(s) from the ledger.

rollSchedule : *([Text] -> Update [HolidayCalendarData]) -> PeriodicSchedule -> [Text] -> Update (Schedule, [HolidayCalendarData])*

Retrieve holiday calendar(s) from the ledger and roll out a schedule. Returns the rolled schedule and the required calendars.

22.3.18 Daml.Finance.Data.V4.Time.DateClock

22.3.18.1 Templates

template `DateClock`

A `DateClock` is a template used to keep track of the current date. It implements the `Time` rule interface to be able to advance and rewind business time. It also implements the `TimeObservable` interface. Specifically, each date `D` is mapped to `D 00:00:00 UTC`. If your use-case involves working across multiple time zones, you may need to define multiple `DateClock` templates with specific time conversions.

Signatory: providers

Field	Type	Description
providers	Parties	The clock's providers.
date	Unit	The clock's date.
id	Id	The clock's identifier.
description	Text	The clock's description.
observers	Parties	Observers.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance `I` for [DateClock](#)

interface instance `I` for [DateClock](#)

22.3.18.2 Data Types

type `T` = [DateClock](#)

Type synonym for `DateClock`.

22.3.18.3 Functions

[dateToDateClockTime](#) : [Date](#) -> [Time](#)

Maps a `Date` to `Time` using the rule in the `DateClock`.

22.3.19 Daml.Finance.Data.V4.Time.DateClock.Types

22.3.19.1 Data Types

data [Unit](#)

A `Date` which can be converted to `Time`. Specifically, each date `D` is mapped to `D 00:00:00 UTC`.

[Unit](#) `Date`

instance [HasUTCTimeConversion](#) `Unit`

instance [Eq](#) `Unit`

instance [Ord Unit](#)

instance [Show Unit](#)

22.3.20 Daml.Finance.Data.V4.Time.DateClockUpdate

22.3.20.1 Templates

template [DateClockUpdateEvent](#)

Event signalling the update of a `DateClock`. It can trigger the execution of lifecycle rules for some instruments.

Signatory: providers

Field	Type	Description
providers	Parties	Providers of the event.
date	Date	The updated clock data.
eventTime	Time	The event time.
id	Id	Event identifier.
description	Text	Event description.
observers	Parties	The clock's observers.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance *I* for [DateClockUpdateEvent](#)

interface instance *I* for [DateClockUpdateEvent](#)

22.3.20.2 Data Types

type *T* = [DateClockUpdateEvent](#)

Type synonym for `DateClockUpdateEvent`.

22.3.21 Daml.Finance.Data.V4.Time.LedgerTime

22.3.21.1 Templates

template [LedgerTime](#)

A `LedgerTime` is a template used to retrieve current ledger time as a `TimeObservable`.

Signatory: providers

Field	Type	Description
providers	Parties	The time providers.
id	Id	The ledger time identifier.
description	Text	The ledger time description.
observers	Parties	Observers.

Choice Archive
Controller: providers
Returns: ()
(no fields)
interface instance *I* for *LedgerTime*

22.3.21.2 Data Types

type *T* = *LedgerTime*
Type synonym for *LedgerTime*.

22.3.22 Daml.Finance.Holding.V4.BaseHolding

22.3.22.1 Templates

template *BaseHolding*

Implementation of a *BaseHolding*. *BaseHolding* implements the interface *Holding.I* (which requires *Lockable.I* and *Disclosure.I* to be implemented), but neither *Fungible.I* nor *Transferable.I*.

Signatory: (DA.Internal.Record.getField @"custodian" account), (DA.Internal.Record.getField @"owner" account), Lockable.getLockers this

Field	Type	Description
instrument	<i>InstrumentKey</i>	The instrument of which units are held.
account	<i>AccountKey</i>	The account at which the holding is held. Defines the holding's owner and custodian.
amount	<i>Decimal</i>	Number of units.
lock	<i>Optional Lock</i>	An optional lock for the holding.
observers	<i>PartiesMap</i>	Observers.

Choice Archive
Controller: (DA.Internal.Record.getField @"custodian" account), (DA.Internal.Record.getField @"owner" account), Lockable.getLockers this
Returns: ()

interface instance *I* for *BaseHolding*
interface instance *I* for *BaseHolding*
interface instance *I* for *BaseHolding*

22.3.22.2 Data Types

type *T* = *BaseHolding*

Type synonym for *BaseHolding*.

22.3.23 Daml.Finance.Holding.V4.Factory

22.3.23.1 Templates

template *Factory*

Implementation of a factory template for holdings.

Signatory: provider

Field	Type	Description
provider	<i>Party</i>	The factory's provider.
id	<i>Id</i>	Identifier for the factory.
observers	<i>PartiesMap</i>	The factory's observers.

Choice Archive

Controller: provider

Returns: ()

(no fields)

interface instance *I* for *Factory*

interface instance *I* for *Factory*

22.3.23.2 Data Types

type *T* = *Factory*

Type synonym for *Factory*.

22.3.24 Daml.Finance.Holding.V4.Fungible

22.3.24.1 Templates

template *Fungible*

Implementation of a fungible holding. The *Fungible* template implements the interface *Fungible.I* (which requires *Holding.I*, *Lockable.I*, and *Disclosure.I* to be implemented), but not the *Transferable.I*.

Signatory: (DA.Internal.Record.getField @"custodian" account), (DA.Internal.Record.getField @"owner" account), Lockable.getLockers this

Field	Type	Description
instrument	InstrumentKey	The instrument of which units are held.
account	AccountKey	The account at which the holding is held. Defines the holding's owner and custodian.
amount	Decimal	Number of units.
lock	Optional Lock	An optional lock for the holding.
observers	PartiesMap	Observers.

Choice Archive

type *T* = *Factory*

Type synonym for *Factory*.

22.3.29 Daml.Finance.Instrument.Bond.V3.Callable.Instrument

22.3.29.1 Templates

template *Instrument*

This template models a callable bond. It pays a fixed or a floating coupon rate at the end of every coupon period (unless the bond has been called). Callability is restricted to some (or all) of the coupon dates. This is specified by a separate schedule.

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	The identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
floatingRate	Optional FloatingRate	A description of the floating rate to be used (if applicable). This supports both Libor and SOFR style reference rates (using a compounded index, e.g. the SOFR Index).
couponRate	Decimal	The fixed coupon rate, per annum. For example, in case of a "3.5% p.a coupon" this should be 0.035. This can also be used as a floating coupon spread. For example, in case of "3M Libor + 0.5%" this should be 0.005.
capRate	Optional Decimal	The maximum coupon rate possible. For example, if "3M Libor + 0.5%" would result in a rate of 2.5%, but capRate is 2.0%, the coupon rate used would be 2.0%.
floorRate	Optional Decimal	The minimum coupon rate possible. For example, if "3M Libor + 0.5%" would result in a rate of -0.2%, but floorRate is 0.0%, the coupon rate used would be 0.0%.
couponSchedule	PeriodicSchedule	The schedule for the periodic coupon payments. The coupon is paid on the <i>last</i> date of each schedule period. In case of a floating rate, the reference rate will be fixed in relation to this schedule (in case of a Libor rate: at the start/end of each period, as specified by FloatingRate). This is the main schedule of the instrument, which drives both the calculation and the payment of coupons. It also defines the issue date and the maturity date of the bond.
callSchedule	PeriodicSchedule	The bond is callable on the <i>last</i> date of each schedule period. For example, if this schedule is the same as the couponSchedule, it means that the bond can be called on each coupon payment date.
noticeDays	Int	The number of business days in advance of the coupon date that the issuer must give notice if it wants to call the bond. The election whether to call or not to call must be done by this date.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the coupon schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
useAdjustedDates-ForDcf	Bool	Configure whether to use adjusted dates (as specified in <i>businessDayAdjustment</i> of the <i>couponSchedule</i>) for day count fractions.
currency	InstrumentKey	The currency of the bond. For example, if the

22.3.35 Daml.Finance.Instrument.Bond.V3.InflationLinked.Instrument

22.3.35.1 Templates

template `Instrument`

This template models an inflation linked bond. It pays an inflation adjusted coupon at the end of every coupon period. The coupon is based on a fixed rate, which is applied to a principal that is adjusted according to an inflation index, for example the Consumer Price Index (CPI) in the U.S. For example: 0.5% p.a. coupon, CPI adjusted principal: At maturity, the greater of the adjusted principal and the original principal is redeemed. For clarity, this only applies to the redemption amount. The coupons are always calculated based on the adjusted principal.

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	An identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
inflationIndexId	Text	The inflation index reference ID. For example, in case of "0.5% p.a. coupon, CPI adjusted principal" this should be a valid reference to the "CPI" index.
inflationIndexBaseValue	Decimal	The value of the inflation index on the first reference date of this bond (called "dated date" on US TIPS). This is used as the base value for the principal adjustment.
couponRate	Decimal	The fixed coupon rate, per annum. For example, in case of a "0.5% p.a. coupon, CPI adjusted principal" this should be 0.005.
periodicSchedule	PeriodicSchedule	The schedule for the periodic coupon payments.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the coupon schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
currency	InstrumentKey	The currency of the bond. For example, if the bond pays in USD this should be a USD cash instrument.
notional	Decimal	The notional of the bond. This is the face value corresponding to one unit of the bond instrument. For example, if one bond unit corresponds to 1000 USD, this should be 1000.0.
observers	PartiesMap	The observers of the instrument.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.54 Daml.Finance.Instrument.StructuredProduct.V0.AutoCallable.Instrument

22.3.54.1 Templates

template *Instrument*

This template models an AutoCallable instrument that pays a conditional coupon. It is an AutoCallable Barrier Reverse Convertible where the KI barrier is observed at maturity. It is a single-underlying product. The instrument is automatically called (redeemed early) if the call barrier is hit. The conditional coupon is paid in each coupon period unless the coupon barrier has been hit. Both the call barrier and the coupon barrier are observed only on the last observation date of each period.

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	An identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
referenceAssetId	Text	The reference asset ID. For example, in case of an AAPL underlying this should be a valid reference to the AAPL fixings to be used for the payoff calculation.
putStrike	Decimal	The strike of the put (as a percentage of the underlying closing price on the first observation date).
couponBarrier	Decimal	The coupon barrier (as a percentage of the underlying closing price on the first observation date).
callBarrier	Decimal	The barrier used to automatically call the instrument (as a percentage of the underlying closing price on the first observation date).
finalBarrier	Decimal	The barrier used to determine the final redemption amount (as a percentage of the underlying closing price on the first observation date).
couponRate	Decimal	The fixed coupon rate, either per annum or per coupon period (depending on the dayCountConvention below).
observationSchedule	PeriodicSchedule	The schedule for the observation dates. These are used to observe the barrier, determine whether the instrument is automatically called and to determine the final redemption amount.
periodicSchedule	PeriodicSchedule	The schedule for the periodic coupon payments.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the coupon schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
currency	InstrumentKey	The currency of the product. For example, if the product pays in USD this should be a USD cash instrument.
notional	Decimal	The notional of the product. This is the face value corresponding to one unit of the product. For example, if one product unit corresponds to 1000 USD, this should be 1000.0.
observers	PartiesMap	The observers of the instrument.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.
prevEvents	[EventData]	A list of previous events that have been lifecycle on this instrument so far.

22.3.58.2 Data Types

type `T` = `Factory`

Type synonym for `Factory`.

22.3.59 Daml.Finance.Instrument.Swap.V0.Asset.Instrument

22.3.59.1 Templates

template `Instrument`

This template models an asset swap. It pays an asset performance vs a fix interest rate at the end of every payment period. It can be used to model equity swaps, some types of commodity swaps (of the form performance vs rate) and swaps with the same payoff on other asset types. The asset leg is described by an observable containing either unadjusted or adjusted fixings (for a price return or a total return swap, respectively). The template calculates the performance for each payment period using this observable. For example: AAPL total return vs 2.5% fix.

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	An identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
underlyings	[Underlying]	The list of underlyings (the basket of reference assets for the asset swap).
ownerReceivesRate	Bool	Indicate whether a holding owner of this instrument receives the rate or the asset leg of the swap.
floatingRate	Optional FloatingRate	A description of the floating rate to be used (if applicable). This supports both Libor and SOFR style reference rates (using a compounded index, e.g. the SOFR Index).
fixRate	Decimal	The interest rate of the fix leg. For example, in case of "AAPL total return vs 2.5% fix" this should be 0.025. This can also be used as a floating rate spread. For example, in case of "3M Libor + 0.5%" this should be 0.005.
periodicSchedule	PeriodicSchedule	The schedule for the periodic swap payments.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the swap payment schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
currency	InstrumentKey	The currency of the swap. For example, if the swap pays in USD this should be a USD cash instrument.
observers	PartiesMap	The observers of the instrument.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.62 Daml.Finance.Instrument.Swap.V0.CreditDefault.Instrument

22.3.62.1 Templates

template *Instrument*

This template models a cash-settled credit default swap. In case of a credit default event it pays (1-recoveryRate), in exchange for a fix rate at the end of every payment period. For example: 2.5% fix vs (1-recoveryRate) if TSLA defaults on a bond payment

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	An identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
defaultProbabilityReferenceId	Text	The reference ID of the default probability observable. For example, in case of protection against a "TSLA bond payment default" this should be a valid reference to the "TSLA default probability".
recoveryRateReferenceId	Text	The reference ID of the recovery rate observable. For example, in case of a "TSLA bond payment default with a 60% recovery rate" this should be a valid reference to the "TSLA bond recovery rate".
ownerReceivesFix	Bool	Indicate whether a holding owner of this instrument receives the fix or the default protection leg of the swap.
fixRate	Decimal	The interest rate of the fix leg. For example, in case of "2.5% fix" this should be 0.025.
periodicSchedule	PeriodicSchedule	The schedule for the periodic swap payments.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the swap payment schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
currency	InstrumentKey	The currency of the swap. For example, if the swap pays in USD this should be a USD cash instrument.
observers	PartiesMap	The observers of the instrument.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.64 Daml.Finance.Instrument.Swap.V0.Currency.Instrument

22.3.64.1 Templates

template `Instrument`

This template models a currency swap. It pays a fix vs fix rate (in different currencies) at the end of every payment period. The principal in the foreign currency is calculated using an fx rate and the principal amount in the base currency. The principal is not exchanged. For example: USD 1000k principal, fx rate 1.10 -> EUR 1100k principal 3% fix rate on USD 1000k vs 2% fix rate on EUR 1100k

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	An identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
ownerReceivesBase	Bool	Indicate whether a holding owner of this instrument receives the base currency leg or the foreign currency leg of the swap.
baseRate	Decimal	The interest rate of the base currency. For example, in case of "3% in USD" this should be 0.03.
foreignRate	Decimal	The interest rate of the foreign currency. For example, in case of "2% in EUR" this should be 0.02.
periodicSchedule	PeriodicSchedule	The schedule for the periodic swap payments.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the swap payment schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
baseCurrency	InstrumentKey	The base currency of the swap. For example, in the case of USD this should be a USD cash instrument.
foreignCurrency	InstrumentKey	The foreign currency of the swap. For example, in case of EUR this should be a EUR cash instrument.
fxRate	Decimal	The fx rate used to convert from the base currency principal amount to the foreign currency principal amount.
observers	PartiesMap	The observers of the instrument.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.66 Daml.Finance.Instrument.Swap.V0.ForeignExchange.Instrument

22.3.66.1 Templates

template `Instrument`

This template models a foreign exchange swap (FX Swap). It has two legs: an initial FX transaction and a final FX transaction. The instrument has a base currency and a foreign currency. The convention is that a holding owner receives the foreign currency in the initial transaction (and pays it in the final transaction). Both FX rates and transaction dates are predetermined between the counterparties. For example: USD 1000k vs EUR 1100k (fx rate: 1.10) today USD 1000k vs EUR 1200k (fx rate: 1.20) in 6 months

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	An identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
firstFxRate	Decimal	The fx rate used for the first swap payment.
finalFxRate	Decimal	The fx rate used for the final swap payment.
issueDate	Date	The date when the swap was issued.
firstPaymentDate	Date	The first payment date of the swap.
maturityDate	Date	The final payment date of the swap.
baseCurrency	InstrumentKey	The base currency of the swap, which will be exchanged to another (foreign) currency on the first payment date. For example, in case of USD this should be a USD cash instrument.
foreignCurrency	InstrumentKey	The foreign currency of the swap. For example, in case of EUR this should be a EUR cash instrument.
observers	PartiesMap	The observers of the instrument.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.68.1 Templates

template *Instrument*

This template models a swap specified by FpML swapStream modules. It can contain one or several legs of different types: fix or floating rates

Signatory: depository, issuer

Field	Type	Description
depository	Party	The depository of the instrument.
issuer	Party	The issuer of the instrument.
id	Id	An identifier of the instrument.
version	Text	The instrument's version.
holdingStandard	HoldingStandard	The holding standard for holdings referencing this instrument.
description	Text	A description of the instrument.
swapStreams	[SwapStream]	Each element describes a stream of swap payments, for example a regular fixed or floating rate.
issuerPartyRef	Text	Used to identify which counterparty is the issuer in the swapStream.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
currencies	[InstrumentKey]	The currencies of the different swap legs, one for each swapStream. For example, if one leg pays in USD this should be a USD cash instrument.
observers	PartiesMap	The observers of the instrument.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

type *C* = *Claim Date Decimal Deliverable Observable***type** *O* = *Observation Date Decimal Observable*

22.3.69.2 Functions

createCalculationPeriodicSchedule : *CalculationPeriodDates* -> *PeriodicSchedule*

Create a schedule for calculation periods.

createPaymentPeriodicSchedule : *SwapStream* -> *PeriodicSchedule*

Create a schedule for payment periods.

getCalendarsAndAdjust : *Date* -> *BusinessDayAdjustments* -> *Party* -> *Party* -> *Update Date*

Retrieve holiday calendars and adjust a date as specified in a *BusinessDayAdjustments* FpML element

adjustDateAccordingToBusinessDayAdjustments : *Date* -> *BusinessDayAdjustments* -> *Party* -> *Party* -> *Update Date*

Adjust a date as specified in a *BusinessDayAdjustments* FpML element (or not at all if *NoAdjustment*)

applyPaymentDaysOffset : [*SchedulePeriod*] -> *PaymentDates* -> [*HolidayCalendarData*] -> [*SchedulePeriod*]

Adjust payment schedule according to *paymentDaysOffset* (if available).

getSingleStubRate : *StubFloatingRate* -> *Date* -> *Optional O*

Define observable part of claim when one specific floating rate is provided for a stub period.

getInterpolatedStubRate : *StubFloatingRate* -> *StubFloatingRate* -> *SchedulePeriod* -> *HolidayCalendarData* -> *BusinessDayConventionEnum* -> *Date* -> *Optional O*

Linearly interpolates two rates within a period, as specified in <https://www.isda.org/a/aWkgE/Linear-interpolation-04022022.pdf>

getStubRateFloating : [*StubFloatingRate*] -> *SchedulePeriod* -> *HolidayCalendarData* -> *BusinessDayConventionEnum* -> *Date* -> *Optional O*

Get the floating stub rate to be used for a stub period.

getStubRate : *StubCalculationPeriodAmount* -> *Bool* -> *SchedulePeriod* -> *HolidayCalendarData* -> *BusinessDayConventionEnum* -> *Bool* -> *Date* -> *Optional O*

Get the stub rate to be used for a stub period. Currently, three main options from the FpML schema are supported:

1. A fix stubRate.
2. One or two floating rates for the stub.
3. No specific stub rate defined -> use the same rate as is used for regular periods.

alignPaymentSchedule : [*SchedulePeriod*] -> [*SchedulePeriod*] -> *Update* [*SchedulePeriod*]

Align the payment schedule with the calculation schedule.

verifyFxScheduleAndGetId : [*SchedulePeriod*] -> *SwapStream* -> *Party* -> *Party* -> *FxLinkedNotionalSchedule* -> *Update* (*Optional Text*, *Optional Decimal*, *Optional* [*Date*])

getFxRateId : [*SchedulePeriod*] -> *SwapStream* -> *Party* -> *Party* -> *Update* (*Optional Text*, *Optional Decimal*, *Optional* [*Date*])

getRateFixingsAndCalendars : *SwapStream* -> *ResetDates* -> [*SchedulePeriod*] -> *Party* -> *Party* -> *Update* ([*Date*], *HolidayCalendarData*)

calculateFixPaymentClaimsFromSwapStream : *FixedRateSchedule* -> *SwapStream* -> *PeriodicSchedule* -> [*SchedulePeriod*] -> [*SchedulePeriod*] -> *Bool* -> *Bool* -> *Deliverable* -> *Party* -> *Party* -> *Optional Text* -> *Optional* [*Date*] -> [(*Decimal*, *Bool*)] -> *Update* [*TaggedClaim*]

Create claims from *swapStream* that describes a fixed coupon stream.

calculatePrincipalExchangePaymentClaims : [\[SchedulePeriod\]](#) -> [Bool](#) -> [Deliverable](#) -> [Optional Text](#) -> [\[\(Decimal, Bool\)\]](#) -> [\[Date\]](#) -> [PrincipalExchanges](#) -> [TaggedClaim](#)
Create principal exchange claims.

roundRate : [Decimal](#) -> [Rounding](#) -> [Decimal](#)

Apply rounding convention to the rate used in a calculation period. Takes a Rounding FpML object as an input:
<https://www.fpml.org/spec/fpml-5-11-3-lcwg-1/html/confirmation/schemaDocumentation/schemas/fpml-5-11-3-lcwg-1.html>

checkRefRateCompounding : [FloatingRateCalculation](#) -> ([Bool](#), [Optional DayCountConventionEnum](#))

Check whether a FloatingRateCalculation uses a reference rate that needs to be compounded. Seems there is no FpML element that specifies this, but that it is implicit in the rate name, for example "USD-SOFR-COMPOUND" If it is a compounded reference rate, also return the daycount convention that was used for the corresponding reference index, e.g. Act360 in the case of the SOFR Index.

calculateFloatingPaymentClaimsFromSwapStream : [FloatingRateCalculation](#) -> [SwapStream](#) -> [PeriodicSchedule](#) -> [\[SchedulePeriod\]](#) -> [\[SchedulePeriod\]](#) -> [Bool](#) -> [Bool](#) -> [Deliverable](#) -> [Party](#) -> [Party](#) -> [Optional Text](#) -> [Optional \[Date\]](#) -> [\[\(Decimal, Bool\)\]](#) -> [Update \[TaggedClaim\]](#)

Create claims from swapStream that describes a floating coupon stream.

calculateClaimsFromSwapStream : [SwapStream](#) -> [PeriodicSchedule](#) -> [\[SchedulePeriod\]](#) -> [\[SchedulePeriod\]](#) -> [Optional SwapStream](#) -> [Bool](#) -> [Bool](#) -> [Deliverable](#) -> [Party](#) -> [Party](#) -> [Update \[TaggedClaim\]](#)

Create claims from swapStream that describes a fixed or floating coupon stream.

22.3.70 Daml.Finance.Instrument.Swap.V0.InterestRate.Factory

22.3.70.1 Templates

template [Factory](#)

Factory template for instrument creation.

Signatory: provider

Field	Type	Description
provider	Party	The factory's provider.
observers	PartiesMap	The factory's observers.

Choice Archive

Controller: provider

Returns: ()

(no fields)

interface instance *I* for [Factory](#)

interface instance *I* for [Factory](#)

22.3.70.2 Data Types

type `T` = `Factory`

Type synonym for `Factory`.

22.3.71 Daml.Finance.Instrument.Swap.V0.InterestRate.Instrument

22.3.71.1 Templates

template `Instrument`

This template models an interest rate swap. It pays a fix vs floating rate at the end of every payment period. The floating leg depends on a reference rate (observed at the beginning of the swap payment period). For example: 3M Euribor vs 2.5% fix.

Signatory: depository, issuer

Field	Type	Description
depository	<code>Party</code>	The depository of the instrument.
issuer	<code>Party</code>	The issuer of the instrument.
id	<code>Id</code>	An identifier of the instrument.
version	<code>Text</code>	The instrument's version.
holdingStandard	<code>HoldingStandard</code>	The holding standard for holdings referencing this instrument.
description	<code>Text</code>	A description of the instrument.
floatingRate	<code>FloatingRate</code>	A description of the floating rate to be used. This supports both Libor and SOFR style reference rates (using a compounded index, e.g. the SOFR Index).
ownerReceivesFix	<code>Bool</code>	Indicate whether a holding owner of this instrument receives the fix or the floating leg of the swap.
fixRate	<code>Decimal</code>	The interest rate of the fix leg. For example, in case of "3M Euribor vs 2.5% fix" this should be 0.025.
periodicSchedule	<code>PeriodicSchedule</code>	The schedule for the periodic swap payments.
holidayCalendarIds	<code>[Text]</code>	The identifiers of the holiday calendars to be used for the swap payment schedule.
calendarDataProvider	<code>Party</code>	The reference data provider to use for the holiday calendar.
dayCountConvention	<code>DayCountConventionEnum</code>	The day count convention used to calculate day count fractions. For example: Act360.
currency	<code>InstrumentKey</code>	The currency of the swap. For example, if the swap pays in USD this should be a USD cash instrument.
observers	<code>PartiesMap</code>	The observers of the instrument.
lastEventTimestamp	<code>Time</code>	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.74.3 Functions

toKey : [View](#) -> [AccountKey](#)

Convert the account's 'View' to its key.

accountKey : [HasToInterface](#) i [Account](#) => i -> [AccountKey](#)

Retrieves the key of an [Account](#).

getKey : [Account](#) -> [AccountKey](#)

credit : [Account](#) -> [Credit](#) -> [Update](#) ([ContractId](#) i)

debit : [Account](#) -> [Debit](#) -> [Update](#) ()

disclose : ([Text](#), [Parties](#)) -> [Party](#) -> [Parties](#) -> [AccountKey](#) -> [Update](#) ([ContractId](#) [Account](#))

Disclose account.

undisclose : ([Text](#), [Parties](#)) -> [Party](#) -> [Parties](#) -> [AccountKey](#) -> [Update](#) ([Optional](#) ([ContractId](#) [Account](#)))

Undisclose account.

exerciseInterfaceByKey : ([HasInterfaceTypeRep](#) i, [HasExercise](#) i c r) => [AccountKey](#) -> [Party](#) -> c -> [Update](#) r

Exercise interface by key. This method can be used to exercise a choice on an [Account](#) given its [AccountKey](#). Requires as input the [AccountKey](#), For example:

```
exerciseInterfaceByKey @Account.I accountKey actor Account.Debit with
  ↪ holdingCid
```

22.3.75 Daml.Finance.Interface.Account.V4.Factory

22.3.75.1 Interfaces

interface [Factory](#)

Interface that allows implementing templates to create accounts.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Create](#)

Create a new account.

Controller: (DA.Internal.Record.getField @"custodian" account), (DA.Internal.Record.getField @"owner" account)

Returns: [ContractId](#) i

Field	Type	Description
account	AccountKey	The account's key.
holdingFactory	HoldingFactoryKey	Associated holding factory for the account.
controllers	Controllers	Controllers of the account.
description	Text	Human readable description of the account.
observers	PartiesMap	The account's observers.

Method create' : [Create](#) -> [Update](#) ([ContractId I](#))

Implementation of `Create` choice.

22.3.75.2 Data Types

type [I](#) = [Factory](#)

Type synonym for `Factory`.

type [V](#) = [View](#)

Type synonym for `View`.

instance [HasFromAnyView](#) [Factory V](#)

22.3.76 Daml.Finance.Interface.Account.V4.Util

22.3.76.1 Functions

fetchAccount : [HasToInterface](#) [t I](#) => [t](#) -> [Update I](#)

Fetch the account of a holding.

getAccount : [HasToInterface](#) [t I](#) => [t](#) -> [AccountKey](#)

Get the account key of a holding.

getCustodian : [HasToInterface](#) [t I](#) => [t](#) -> [Party](#)

Get the custodian of a holding.

getOwner : [HasToInterface](#) [t I](#) => [t](#) -> [Party](#)

Get the owner of a holding.

22.3.77 Daml.Finance.Interface.Claims.V4.Claim

22.3.77.1 Interfaces

interface [Claim](#)

Interface implemented by templates that can be represented as Contingent Claims.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetClaims](#)

Retrieves the list of claims representing the instrument. This might involve fetching reference data, such as calendars, on which the actor must have visibility.

Controller: actor

Returns: [[TaggedClaim](#)]

Field	Type	Description
actor	Party	The party retrieving the claims.

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Method [getClaims](#) : [GetClaims](#) -> [Update](#) [[TaggedClaim](#)]

The list of claims representing the instrument.

22.3.77.2 Data Types

type [I](#) = [Claim](#)

Type synonym for [Claim](#).

type [V](#) = [View](#)

Type synonym for [View](#).

instance [HasFromAnyView](#) [Claim](#) [V](#)

data [View](#)

View for [Claim](#).

[View](#)

Field	Type	Description
acquisitionTime	Time	The claim's acquisition time.

instance [Eq](#) [View](#)

instance [Show View](#)

22.3.77.3 Functions

getClaims : [Claim](#) -> [GetClaims](#) -> [Update](#) [[TaggedClaim](#)]

getClaim : [Party](#) -> [Claim](#) -> [Update C](#)

Retrieves the single claim representing the template. An error is thrown if there are zero or more than one claims.

getAcquisitionTime : [Claim](#) -> [Time](#)

Retrieves the claim's acquisition time.

22.3.78 Daml.Finance.Interface.Claims.V4.Dynamic.Instrument

22.3.78.1 Interfaces

interface [Instrument](#)

Interface implemented by instruments that create Contingent Claims trees on-the-fly (i.e., the tree is not stored on disk as part of a contract, but created and processed in-memory).

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [CreateNewVersion](#)

Create a new version of an instrument, using a new lastEventTimestamp and a list of previous elections (if applicable).

Controller: (DA.Internal.Record.getField @"lifecycler" (view this))

Returns: [ContractId](#) [Instrument](#)

Field	Type	Description
version	Text	The new version of the instrument.
lastEventTimes- tamp	Time	The new lastEventTimestamp of the instru- ment.
prevEvents	[EventData]	A list of previous elections that have been lifecycled on this instrument so far.

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Method createNewVersion : [CreateNewVersion](#) -> [Update](#) ([ContractId](#) [Instrument](#))

22.3.78.2 Data Types

type *I* = *Instrument*

Type synonym for `Instrument`.

type *V* = *View*

Type synonym for `View`.

instance `HasFromAnyView Instrument V`

data *View*

View for `Instrument`.

View

Field	Type	Description
lifecycler	<i>Party</i>	Party performing the lifecycling.
lastEventTimestamp	<i>Time</i>	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.
prevEvents	<code>[EventData]</code>	A list of previous elections that have been lifecycled on this instrument so far.

instance `Eq View`

instance `Show View`

22.3.78.3 Functions

createNewVersion : *Instrument* -> *CreateNewVersion* -> *Update* (`ContractId Instrument`)

22.3.79 Daml.Finance.Interface.Claims.V4.Types

22.3.79.1 Data Types

type *C* = *Claim Time Decimal Deliverable Observable*

The specialized claim type.

type *Deliverable* = *InstrumentKey*

Type used to reference assets in the claim tree.

type *Observable* = *Text*

Type used to reference observables in the claim tree.

data *Pending*

Type used to record pending payments.

Pending

Field	Type	Description
t	Time	
tag	Text	
instrument	Deliverable	
amount	Decimal	

instance [Eq Pending](#)

instance [Show Pending](#)

data [TaggedClaim](#)

A claim and a textual tag.

[TaggedClaim](#)

Field	Type	Description
claim	C	
tag	Text	

instance [Eq TaggedClaim](#)

instance [Show TaggedClaim](#)

instance HasMethod [Claim](#) "getClaims" ([GetClaims](#) -> [Update](#) [[TaggedClaim](#)])

22.3.80 Daml.Finance.Interface.Data.V4.Numeric.Observation

22.3.80.1 Interfaces

interface [Observation](#)

Interface for a time-dependent numeric [Observation](#), where the values are explicitly stored on-ledger.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party fetching the view.

22.3.80.2 Data Types

type *I* = *Observation*

Type synonym for `Observation`.

instance `HasMethod Factory "create"` (*Create* -> *Update* (*ContractId I*))

type *V* = *View*

Type synonym for `View`.

instance `HasFromAnyView Observation V`

data *View*

View for `Observation`.

View

Field	Type	Description
provider	<i>Party</i>	The reference data provider.
id	<i>Id</i>	A textual identifier.
observations	<i>Map Time Decimal</i>	The time-dependent values.
observers	<i>PartiesMap</i>	Observers.

22.3.81 Daml.Finance.Interface.Data.V4.Numeric.Observation.Factory

22.3.81.1 Interfaces

interface *Factory*

Factory contract used to create, remove and view a `Numeric.Observation`.

viewtype *V*

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *Create*

Create an `Observation`.

Controller: `provider`

Returns: *ContractId I*

Field	Type	Description
provider	<i>Party</i>	The reference data provider.
id	<i>Id</i>	A textual identifier.
observations	<i>Map Time Decimal</i>	The time-dependent values.
observers	<i>PartiesMap</i>	Observers.

Method `create'` : *Create* -> *Update* (*ContractId I*)

Implementation of `Create` choice.

22.3.81.2 Data Types

type *F* = *Factory*

type *I* = *Factory*

Type synonyms for *Factory*.

type *V* = *View*

Type synonym for *View*.

instance *HasFromAnyView Factory V*

data *View*

View

Field	Type	Description
provider	<i>Party</i>	The provider of the <i>Factory</i> .
observers	<i>PartiesMap</i>	The observers of the <i>Factory</i> .

instance *Eq View*

instance *Show View*

22.3.81.3 Functions

create' : *Factory* -> *Create* -> *Update* (*ContractId I*)

22.3.82 Daml.Finance.Interface.Data.V4.Reference.HolidayCalendar

22.3.82.1 Interfaces

interface *HolidayCalendar*

Interface for contracts storing holiday calendar data on the ledger.

viewtype *V*

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party fetching the view.

Choice *UpdateCalendar*

Updates the holiday calendar.

Controller: (DA.Internal.Record.getField @"provider" (view this))

Returns: *ContractId HolidayCalendar*

Field	Type	Description
newCalendar	HolidayCalendarData	The new HolidayCalendarData.

Method updateCalendar : [UpdateCalendar](#) -> [Update](#) ([ContractId](#) [HolidayCalendar](#))
Updates the holiday calendar.

22.3.82.2 Data Types

type [I](#) = [HolidayCalendar](#)

Type synonym for [HolidayCalendar](#).

instance [HasMethod](#) [Factory](#) "create" ([Create](#) -> [Update](#) ([ContractId](#) [I](#)))

type [V](#) = [View](#)

Type synonym for [View](#).

instance [HasFromAnyView](#) [HolidayCalendar](#) [V](#)

data [View](#)

View for [HolidayCalendar](#).

[View](#)

Field	Type	Description
provider	Party	The parties providing the HolidayCalendar .
calendar	HolidayCalendarData	Holiday Calendar Data used to define holidays.

22.3.82.3 Functions

[updateCalendar](#) : [HolidayCalendar](#) -> [UpdateCalendar](#) -> [Update](#) ([ContractId](#) [HolidayCalendar](#))

22.3.83 Daml.Finance.Interface.Data.V4.Reference.HolidayCalendar.Factory

22.3.83.1 Interfaces

interface [Factory](#)

Interface that allows implementing templates to create holiday calendars.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Create](#)

Create a new Holiday Calendar.

Controller: provider

Returns: [ContractId I](#)

Field	Type	Description
calendar	HolidayCalendarData	Holiday Calendar Data used to define holidays.
observers	PartiesMap	Observers.
provider	Party	The calendar's provider.

Method create' : [Create](#) -> [Update](#) ([ContractId I](#))

Implementation of `Create` choice.

22.3.83.2 Data Types

type [F](#) = [Factory](#)

type [I](#) = [Factory](#)

Type synonyms for `Factory`.

type [V](#) = [View](#)

Type synonym for `View`.

instance [HasFromAnyView](#) [Factory V](#)

data [View](#)

[View](#)

Field	Type	Description
provider	Party	The provider of the <code>Factory</code> .

instance [Eq](#) [View](#)

instance [Show](#) [View](#)

22.3.83.3 Functions

create' : [Factory](#) -> [Create](#) -> [Update](#) ([ContractId I](#))

22.3.84 Daml.Finance.Interface.Data.V4.Reference.Time

This module defines an interface for `BusinessTime` rules, which are contracts to control and keep track of business time.

22.3.84.1 Interfaces

interface *Time*

An interface to manage and control business time. Controlled time rules (i.e. clocks) are managed by entities that have control certain business time events. These can be trading-open / -close on an exchange, start-of-day / end-of-day events of a trading desk, or just a daily clock tick to signal the passing of aticking. Intervals in which the clock "ticks" don't have to be regular, and can e.g. consider business days only.

viewtype *V*

Choice *Advance*

Advance time to its next state.

Controller: (DA.Internal.Record.getField @"providers" (view this))

Returns: ([ContractId Time](#), [ContractId Event](#))

Field	Type	Description
eventId	<i>Id</i>	Event identifier.
eventDescription	<i>Text</i>	Event description.

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party retrieving the view.

Choice *Rewind*

Rewind time to its previous state.

Controller: (DA.Internal.Record.getField @"providers" (view this))

Returns: ([ContractId Time](#), [ContractId Event](#))

Field	Type	Description
eventId	<i>Id</i>	Event identifier.
eventDescription	<i>Text</i>	Event description.

Method advance : [ContractId Time](#) -> *Advance* -> *Update* ([ContractId Time](#), [ContractId Event](#))

Implementation of the *Advance* choice.

Method rewind : [ContractId Time](#) -> *Rewind* -> *Update* ([ContractId Time](#), [ContractId Event](#))

Implementation of the *Rewind* choice.

22.3.84.2 Data Types

type *I* = *Time*

Type synonym for *Time*.

type *V* = *View*

Type synonym for *View*.

instance *HasFromAnyView Time V*

data *View*

View for *Time*.

View

Field	Type	Description
providers	<i>Parties</i>	Parties controlling time.
id	<i>Id</i>	Textual identifier for the time rule.

instance *Eq View*

instance *Show View*

22.3.84.3 Functions

advance : *Time* -> *ContractId Time* -> *Advance* -> *Update* (*ContractId Time*, *ContractId Event*)

rewind : *Time* -> *ContractId Time* -> *Rewind* -> *Update* (*ContractId Time*, *ContractId Event*)

22.3.85 Daml.Finance.Interface.Holding.V4.Factory

22.3.85.1 Interfaces

interface *Factory*

Holding factory contract used to create (credit) holdings.

viewtype *V*

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *Create*

Create a holding on the instrument in the corresponding account.

Controller: (DA.Internal.Record.getField @"custodian" account), (DA.Internal.Record.getField @"owner" account)

Returns: *ContractId I*

Field	Type	Description
instrument	InstrumentKey	The instrument of which units are held.
account	AccountKey	The account at which the holding is held. Defines the holding's owner and custodian.
amount	Decimal	Number of units.
observers	PartiesMap	Observers of the holding to be credited.

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party fetching the view.

Choice [Remove](#)

Archive the factory.

Controller: signatory this

Returns: ()

(no fields)

Method create' : [Create](#) -> [Update](#) ([ContractId](#) *I*)

Implementation of `Create` choice.

Method getKey : [HoldingFactoryKey](#)

Get the unique key of the `HoldingFactory`.

22.3.85.2 Data Types

type *I* = [Factory](#)

Type synonym for `Factory`.

type *R* = `Reference`

Type synonym for `Reference`. This type is currently used as a work-around given the lack of interface keys.

type *V* = [View](#)

Type synonym for `View`.

instance [HasFromAnyView](#) [Factory](#) *V*

data [View](#)

[View](#)

Field	Type	Description
provider	Party	The provider of the <code>Factory</code> .
id	<i>Id</i>	Identifier for the holding factory.

instance [HasInterfaceKey](#) [Factory](#) [View](#) [HoldingFactoryKey](#) [Reference](#) [GetCid](#) [SetCid](#) [SetObservers](#) [GetView](#)

instance [Eq](#) [View](#)

instance [Show View](#)

22.3.85.3 Functions

toKey : [View](#) -> [HoldingFactoryKey](#)

Convert the account's 'View' to its key.

holdingFactoryKey : [HasToInterface](#) i [Factory](#) => i -> [HoldingFactoryKey](#)

Retrieves the key of a [Factory](#).

getKey : [Factory](#) -> [HoldingFactoryKey](#)

create' : [Factory](#) -> [Create](#) -> [Update](#) ([ContractId](#) l)

createFactory : ([HasCreate](#) f, [HasToInterface](#) f [Factory](#)) => f -> [Update](#) ([ContractId](#) [Factory](#))

Create factory including reference.

disclose : ([Text](#), [Parties](#)) -> [Party](#) -> [Parties](#) -> [HoldingFactoryKey](#) -> [Update](#) ([ContractId](#) [Factory](#))

Disclose factory.

undisclose : ([Text](#), [Parties](#)) -> [Party](#) -> [Parties](#) -> [HoldingFactoryKey](#) -> [Update](#) ([Optional](#) ([ContractId](#) [Factory](#))))

Undisclose factory.

exerciseInterfaceByKey : ([HasInterfaceTypeRep](#) i, [HasExercise](#) i c r) => [HoldingFactoryKey](#) -> [Party](#) -> c -> [Update](#) r

Exercise interface by key. This method can be used to exercise a choice on a [Factory](#) given its [HoldingFactoryKey](#). Requires as input the [HoldingFactoryKey](#), the actor exercising the choice, and the choice arguments. For example:

```
exerciseInterfaceByKey @HoldingFactory.I holdingFactoryKey actor
  HoldingFactory.Create with instrument; account; amount; observers
```

22.3.86 Daml.Finance.Interface.Holding.V4.Fungible

22.3.86.1 Interfaces

interface [Fungible](#)

Interface for a fungible holding.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party fetching the view.

Choice [Merge](#)

Merge multiple fungible contracts into a single fungible contract.

Controller: (DA.Internal.Record.getField @"modifiers" (view this))

Returns: [ContractId Fungible](#)

Field	Type	Description
fungibleCids	[ContractId Fungible]	The fungible contracts to merge which will get consumed.

Choice [Split](#)

Split a fungible contract into multiple contracts by amount.

Controller: (DA.Internal.Record.getField @"modifiers" (view this))

Returns: [SplitResult](#)

Field	Type	Description
amounts	[Decimal]	The quantities to split the fungible asset by, creating a new contract per amount.

Method merge : [Merge](#) -> [Update](#) ([ContractId Fungible](#))

Implementation of the `Merge` choice.

Method split : [Split](#) -> [Update SplitResult](#)

Implementation of the `Split` choice.

22.3.86.2 Data Types

type [I](#) = [Fungible](#)

Type synonym for `Fungible`.

data [SplitResult](#)

Result of a call to `Split`.

[SplitResult](#)

Field	Type	Description
splitCids	[ContractId Fungible]	The contract ids for the split holdings.
rest	Optional (ContractId Fungible)	Contract id for the holding on the remaining amount. It is <code>None</code> when the split is exact.

instance [Eq SplitResult](#)

instance [Show SplitResult](#)

instance `HasMethod` [Fungible](#) "split" ([Split](#) -> [Update SplitResult](#))

type [V](#) = [View](#)

Type synonym for `View`.

instance [HasFromAnyView Fungible V](#)

data [View](#)

View for `Fungible`.

[View](#)

Field	Type	Description
modifiers	Parties	Parties which have the authorization to modify a fungible asset.

instance [Eq View](#)

instance [Show View](#)

22.3.86.3 Functions

[split](#) : [Fungible](#) -> [Split](#) -> [Update SplitResult](#)

[merge](#) : [Fungible](#) -> [Merge](#) -> [Update](#) ([ContractId Fungible](#))

22.3.87 Daml.Finance.Interface.Holding.V4.Holding

22.3.87.1 Interfaces

interface [Holding](#)

Holding interface.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [V](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

22.3.87.2 Data Types

type [I](#) = [Holding](#)

Type synonym for `Holding`.

instance `HasMethod` [Account](#) "credit" ([Credit](#) -> [Update](#) ([ContractId I](#)))

instance `HasMethod` [Factory](#) "create" ([Create](#) -> [Update](#) ([ContractId I](#)))

instance `HasMethod` [Batch](#) "cancel" ([Cancel](#) -> [Update](#) [[ContractId I](#)])

instance `HasMethod` [Batch](#) "settle" ([Settle](#) -> [Update](#) [[ContractId I](#)])

instance `HasMethod` [Instruction](#) "allocate" ([Allocate](#) -> [Update](#) ([ContractId Instruction](#), [Optional](#) ([ContractId I](#))))

```
instance HasMethod Instruction "cancel" (Cancel -> Update (Optional (ContractId l)))  
instance HasMethod Instruction "execute" (Execute -> Update (Optional (ContractId l)))
```

type *V* = *View*

Type synonym for *View*.

```
instance HasFromAnyView Holding V
```

data *View*

View for *Holding*.

View

Field	Type	Description
instrument	<i>InstrumentKey</i>	Instrument being held.
account	<i>AccountKey</i>	Key of the account holding the assets.
amount	<i>Decimal</i>	Size of the holding.

```
instance Eq View
```

```
instance Show View
```

22.3.88 Daml.Finance.Interface.Holding.V4.Transferable

22.3.88.1 Interfaces

interface *Transferable*

An interface representing a contract where ownership can be transferred to other parties.

viewtype *View*

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party retrieving the view.

Choice *Transfer*

Transfer a contract to a new owner.

Controller: actors

Returns: *ContractId Transferable*

Field	Type	Description
actors	<i>Parties</i>	Parties authorizing the transfer.
newOwnerAccount	<i>AccountKey</i>	The new owner's account.

Method transfer : [ContractId I -> Transfer -> Update \(ContractId Transferable\)](#)

Implementation of the `Transfer` choice.

22.3.88.2 Data Types

type [I](#) = [Transferable](#)

Type synonym for `Transferable`.

instance `HasMethod` [Transferable](#) "transfer" ([ContractId I -> Transfer -> Update \(ContractId Transferable\)](#))

type [V](#) = [View](#)

Type synonym for `View`.

data [View](#)

View for `Transferable`.

[View](#)

(no fields)

instance `Eq` [View](#)

instance `Show` [View](#)

instance `HasFromAnyView Transferable` [View](#)

22.3.88.3 Functions

[transfer](#) : [Transferable -> ContractId I -> Transfer -> Update \(ContractId Transferable\)](#)

22.3.89 Daml.Finance.Interface.Holding.V4.Util

22.3.89.1 Functions

[getInstrument](#) : `HasToInterface t I => t -> InstrumentKey`

Get the key of a holding.

[getAmount](#) : `HasToInterface t I => t -> Decimal`

Get the amount of a holding.

[disclose](#) : (`HasInterfaceTypeRep i`, `HasToInterface i I`, `HasFromInterface i I`) => (`Text`, `Parties`) -> `Parties`
-> [ContractId i -> Update \(ContractId i\)](#)

Disclose a holding.

[undisclose](#) : (`HasInterfaceTypeRep i`, `HasToInterface i I`, `HasFromInterface i I`) => (`Text`, `Parties`) -> `Parties`
-> [ContractId i -> Update \(Optional \(ContractId i\)\)](#)

Undisclose a holding.

22.3.90 Daml.Finance.Interface.Instrument.Base.V4.Instrument

22.3.90.1 Interfaces

interface *Instrument*

Base interface for all instruments. This interface does not define any lifecycling logic.

viewtype *V*

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party retrieving the view.

Choice *Remove*

Archive the instrument.

Controller: signatory this

Returns: ()

(no fields)

Method *getKey* : *InstrumentKey*

Get the unique key for the *Instrument*.

22.3.90.2 Data Types

type *I* = *Instrument*

Type synonym for *Instrument*.

type *Q* = *Quantity InstrumentKey Decimal*

Instrument quantity.

type *R* = *Reference*

Type synonym for *Reference*. This type is currently used as a work-around given the lack of interface keys.

type *V* = *View*

Type synonym for *View*.

instance *HasFromAnyView Instrument V*

data *View*

View for *Instrument*.

View

Field	Type	Description
issuer	Party	The instrument's issuer.
depository	Party	The instrument's depository.
id	Id	The instrument's identifier.
version	Text	A textual instrument version.
holdingStandard	Holding-Standard	The holding standard for holdings referencing this instrument.
description	Text	A human readable description of the instrument.
validAsOf	Time	Timestamp as of which the instrument is valid. This usually coincides with the timestamp of the event that creates the instrument. It usually does not coincide with ledger time. This is required for life-cycling of some instruments, in order to keep track of the last time the instrument was lifecycled. For instruments where this is not applicable, it can be set to the current time.

instance [HasInterfaceKey](#) [Instrument](#) [View](#) [InstrumentKey](#) [Reference](#) [GetCid](#) [SetCid](#) [SetObservers](#) [GetView](#)

instance [Eq](#) [View](#)

instance [Show](#) [View](#)

22.3.90.3 Functions

toKey : [V](#) -> [InstrumentKey](#)

Convert the instrument's View to its key.

instrumentKey : [HasToInterface](#) [i](#) [Instrument](#) => [i](#) -> [InstrumentKey](#)

Retrieves the key of an [Instrument](#).

getKey : [Instrument](#) -> [InstrumentKey](#)

qty : [Decimal](#) -> [InstrumentKey](#) -> [Q](#)

Wraps an amount and an instrument key into an instrument quantity.

scale : [Decimal](#) -> [Q](#) -> [Q](#)

Scale [Quantity](#) by the provided factor.

fetchInstrument : [HasToInterface](#) [t](#) [I](#) => [t](#) -> [Update](#) [Instrument](#)

Fetch instrument from holding.

exerciseInterfaceByKey : ([HasInterfaceTypeRep](#) [i](#), [HasExercise](#) [i](#) [c](#) [r](#)) => [InstrumentKey](#) -> [Party](#) -> [c](#) -> [Update](#) [r](#)

Exercise interface by key. This method can be used to exercise a choice on an [Instrument](#) given its [InstrumentKey](#). Requires as input the [InstrumentKey](#), the actor exercising the choice, and the choice arguments.

22.3.91 Daml.Finance.Interface.Instrument.Bond.V3.Callable.Factory

22.3.91.1 Interfaces

interface [Factory](#)

Factory interface to instantiate callable bond instruments.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Create](#)

Create a new instrument.

Controller: (DA.Internal.Record.getField @"depository" (DA.Internal.Record.getField @"instrument" callable)), (DA.Internal.Record.getField @"issuer" (DA.Internal.Record.getField @"instrument" callable))

Returns: [ContractId I](#)

Field	Type	Description
callable	Callable	Attributes to create a callable rate bond.
observers	PartiesMap	The instrument's observers.

Method create' : [Create](#) -> [Update](#) ([ContractId I](#))

Implementation of [Create](#) choice.

22.3.91.2 Data Types

type [I](#) = [Factory](#)

Type synonym for [Factory](#).

type [V](#) = [View](#)

Type synonym for [View](#).

instance [HasFromAnyView](#) [Factory V](#)

data [View](#)

View of [Factory](#).

[View](#)

Field	Type	Description
provider	Party	The provider of the Factory .

instance [Eq](#) [View](#)

instance [Show](#) [View](#)

22.3.91.3 Functions

create' : [Factory](#) -> [Create](#) -> [Update](#) ([ContractId I](#))

22.3.92 Daml.Finance.Interface.Instrument.Bond.V3.Callable.Instrument

22.3.92.1 Interfaces

interface [Instrument](#)

Instrument interface representing a callable bond.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [V](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

22.3.92.2 Data Types

type [I](#) = [Instrument](#)

Type synonym for [Instrument](#).

instance [HasMethod](#) [Factory](#) "create" ([Create](#) -> [Update](#) ([ContractId I](#)))

type [V](#) = [View](#)

Type synonym for [View](#).

instance [HasFromAnyView](#) [Instrument](#) [V](#)

data [View](#)

View of [Instrument](#).

[View](#)

Field	Type	Description
callable	Callable	Attributes of a callable bond.

instance [Eq](#) [View](#)

instance [Show](#) [View](#)

22.3.93 Daml.Finance.Interface.Instrument.Bond.V3.Callable.Types

22.3.93.1 Data Types

data *Callable*

Describes the attributes of a Callable Bond.

Callable

Field	Type	Description
instrument	InstrumentKey	The instrument's key.
description	Text	The description of the bond.
floatingRate	Optional FloatingRate	A description of the floating rate to be used (if applicable). This supports both Libor and SOFR style reference rates (using a compounded index, e.g. the SOFR Index).
couponRate	Decimal	The fixed coupon rate, per annum. For example, in case of a "3.5% p.a coupon" this should be 0.035. This can also be used as a floating coupon spread. For example, in case of "3M Libor + 0.5%" this should be 0.005.
capRate	Optional Decimal	The maximum coupon rate possible. For example, if "3M Libor + 0.5%" would result in a rate of 2.5%, but capRate is 2.0%, the coupon rate used would be 2.0%.
floorRate	Optional Decimal	The minimum coupon rate possible. For example, if "3M Libor + 0.5%" would result in a rate of -0.2%, but floorRate is 0.0%, the coupon rate used would be 0.0%.
couponSchedule	Periodic-Schedule	The schedule for the periodic coupon payments. The coupon is paid on the last date of each schedule period. In case of a floating rate, the reference rate will be fixed in relation to this schedule (at the start/end of each period, as specified by FloatingRate). This is the main schedule of the instrument, which drives both the calculation and the payment of coupons. It also defines the issue date and the maturity date of the bond.
callSchedule	Periodic-Schedule	The bond is callable on the last date of each schedule period. For example, if this schedule is the same as the periodicSchedule, it means that the bond can be called on each coupon payment date.
noticeDays	Int	The number of business days in advance of the coupon date that the issuer must give notice if it wants to call the bond. The election whether to call or not to call must be done by this date.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the coupon schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCount-ConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
useAdjustedDatesForDayCount	Bool	Configure whether to use adjusted dates (as specified in <i>businessDayAdjustment</i> of the <i>couponSchedule</i>) for day count fractions.
currency	InstrumentKey	The currency of the bond. For example

instance [Eq Callable](#)

instance [Show Callable](#)

22.3.94 Daml.Finance.Interface.Instrument.Bond.V3.FixedRate.Factory

22.3.94.1 Interfaces

interface [Factory](#)

Factory interface to instantiate fixed-rate bond instruments.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Create](#)

Create a new instrument.

Controller: (DA.Internal.Record.getField @"depository" (DA.Internal.Record.getField @"instrument" fixedRate)), (DA.Internal.Record.getField @"issuer" (DA.Internal.Record.getField @"instrument" fixedRate))

Returns: [ContractId I](#)

Field	Type	Description
fixedRate	FixedRate	Attributes to create a fixed rate bond.
observers	PartiesMap	The instrument's observers.

Method create' : Create -> Update ([ContractId I](#))

Implementation of [Create](#) choice.

22.3.96.1 Data Types

data [FixedRate](#)

Describes the attributes of a Fixed Rate Bond.

[FixedRate](#)

Field	Type	Description
instrument	InstrumentKey	The instrument's key.
description	Text	The description of the bond.
couponRate	Decimal	The fixed coupon rate, per annum. For example, in case of a "3.5% p.a. coupon" this should be 0.035.
periodicSchedule	PeriodicSchedule	The schedule for the periodic coupon payments.
holidayCalendars	[Text]	The identifiers of the holiday calendars to be used for the coupon schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
currency	InstrumentKey	The currency of the bond. For example, if the bond pays in USD this should be a USD cash instrument.
notional	Decimal	The notional of the bond. This is the face value corresponding to one unit of the bond instrument. For example, if one bond unit corresponds to 1000 USD, this should be 1000.0.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.99 Daml.Finance.Interface.Instrument.Bond.V3.FloatingRate.Types

22.3.99.1 Data Types

data *FloatingRate*

Describes the attributes representing a floating rate bond.

FloatingRate

Field	Type	Description
instrument	<i>InstrumentKey</i>	The instrument's key.
description	<i>Text</i>	The description of the bond.
floatingRate	<i>FloatingRate</i>	A description of the floating rate to be used. This supports both Libor and SOFR style reference rates (using a compounded index, e.g. the SOFR Index).
couponSpread	<i>Decimal</i>	The floating rate coupon spread. For example, in case of "3M Euribor + 0.5%" this should be 0.005.
periodicSchedule	<i>PeriodicSchedule</i>	The schedule for the periodic coupon payments.
holidayCalendars	<i>[Text]</i>	The identifiers of the holiday calendars to be used for the coupon schedule.
calendarDataProvider	<i>Party</i>	The reference data provider to use for the holiday calendar.
dayCountConvention	<i>DayCountConventionEnum</i>	The day count convention used to calculate day count fractions. For example: Act360.
currency	<i>InstrumentKey</i>	The currency of the bond. For example, if the bond pays in USD this should be a USD cash instrument.
notional	<i>Decimal</i>	The notional of the bond. This is the face value corresponding to one unit of the bond instrument. For example, if one bond unit corresponds to 1000 USD, this should be 1000.0.
lastEventTimestamp	<i>Time</i>	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

22.3.107.1 Interfaces

interface [Instrument](#)

An interface for a generic equity instrument.

viewtype [V](#)

Choice `Archive`

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [DeclareDistribution](#)

Declare a distribution (e.g. a dividend or a rights issue) to shareholders.

Controller: (DA.Internal.Record.getField @"issuer" (view \$ toInterface @BaseInstrument.I this))

Returns: [ContractId I](#)

Field	Type	Description
id	Id	Event identifier of the dividend distribution.
description	Text	Description of the dividend event.
effectiveTime	Time	Time at which the dividend is distributed.
newInstrument	InstrumentKey	Instrument held after the dividend distribution (i.e. "ex-dividend" stock).
perUnitDistribution	[InstrumentQuantity]	Distributed quantities per unit held.

Choice [DeclareReplacement](#)

Declare a replacement event, where units of the instrument are replaced by a basket of other instruments.

Controller: (DA.Internal.Record.getField @"issuer" (view \$ toInterface @BaseInstrument.I this))

Returns: [ContractId I](#)

Field	Type	Description
id	Id	Distribution Id.
description	Text	Description of the replacement event.
effectiveTime	Time	Time the replacement is to be executed.
perUnitReplacement	[InstrumentQuantity]	Payout offered to shareholders per held share.

Choice [DeclareStockSplit](#)

Declare a stock split.

Controller: (DA.Internal.Record.getField @"issuer" (view \$ toInterface @BaseInstrument.I this))

Returns: [ContractId I](#)

Field	Type	Description
id	Id	Event identifier of the stock split.
description	Text	Description of the stock split event.
effectiveTime	Time	Time at which the stock split is effective.
newInstrument	InstrumentKey	Instrument to be held after the stock split is executed.
adjustmentFactor	Decimal	Adjustment factor for the stock split.

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Method `declareDistribution` : [DeclareDistribution](#) -> [Update \(ContractId I\)](#)

Implementation for the `DeclareDistribution` choice.

Method `declareReplacement` : [DeclareReplacement](#) -> [Update](#) ([ContractId](#) *l*)

Implementation for the `DeclareReplacement` choice.

Method `declareStockSplit` : [DeclareStockSplit](#) -> [Update](#) ([ContractId](#) *l*)

22.3.116 Daml.Finance.Interface.Instrument.Option.V0.Dividend.Election.Factory

22.3.116.1 Interfaces

interface [Factory](#)

Factory interface to instantiate elections on generic instruments.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Create](#)

Create a new Election.

Controller: actors

Returns: [ContractId I](#)

Field	Type	Description
actors	Parties	Parties calling the Create choice.
elector	Party	Parties on behalf of which the election is made.
counterparty	Party	Faces the elector in the Holding .
provider	Party	Party that signs the election (together with the elector).
id	Id	The identifier for an election.
description	Text	A description of the instrument.
claimType	ElectionType-Enum	The election type corresponding to the elected sub-tree.
electorIsOwner	Bool	True if election is on behalf of the owner of the holding, False otherwise.
electionTime	Time	Time at which the election is put forward.
observers	PartiesMap	Observers of the election.
amount	Decimal	Number of instrument units to which the election applies.
instrument	InstrumentKey	The instrument to which the election applies.

Method [create'](#) : [Create](#) -> [Update](#) ([ContractId I](#))

Implementation of [Create](#) choice.

22.3.126 Daml.Finance.Interface.Instrument.StructuredProduct.V0.Auto-Callable.Types

22.3.126.1 Data Types

data *AutoCallable*

Describes the attributes of an `AutoCallable` instrument that pays a conditional coupon.

AutoCallable

Field	Type	Description
instrument	InstrumentKey	The instrument's key.
description	Text	The description of the option.
referenceAssetId	Text	The reference asset ID. For example, in case of an AAPL underlying this should be a valid reference to the AAPL fixings to be used for the payoff calculation.
putStrike	Decimal	The strike of the put (as a percentage of the underlying closing price on the first observation date).
couponBarrier	Decimal	The coupon barrier (as a percentage of the underlying closing price on the first observation date).
callBarrier	Decimal	The barrier used to automatically call the instrument (as a percentage of the underlying closing price on the first observation date).
finalBarrier	Decimal	The barrier used to determine the final redemption amount (as a percentage of the underlying closing price on the first observation date).
couponRate	Decimal	The fixed coupon rate, either per annum or per coupon period (depending on the dayCountConvention below).
observationSchedule	PeriodicSchedule	The schedule for the observation dates. These are used to observe the barrier, determine whether the instrument is automatically called and to determine the final redemption amount.
periodicSchedule	PeriodicSchedule	The schedule for the periodic coupon payments.
holidayCalendarIds	[Text]	The identifiers of the holiday calendars to be used for the coupon schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
currency	InstrumentKey	The currency of the product. For example, if the product pays in USD this should be a USD cash instrument.
notional	Decimal	The notional of the product. This is the face value corresponding to one unit of the product. For example, if one product unit corresponds to 1000 USD, this should be 1000.0.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.
prevEvents	[EventData]	A list of previous events that have been lifecycled on this instrument so far.

22.3.139.1 Data Types

data [CurrencySwap](#)

Describes the attributes of a Currency swap.

[CurrencySwap](#)

Field	Type	Description
instrument	InstrumentKey	The instrument's key.
description	Text	The description of the swap.
ownerReceives-Base	Bool	Indicate whether a holding owner of this instrument receives the base currency leg or the foreign currency leg of the swap.
baseRate	Decimal	The interest rate of the base currency. For example, in case of "3% in USD" this should be 0.03.
foreignRate	Decimal	The interest rate of the foreign currency. For example, in case of "2% in EUR" this should be 0.02.
periodicSchedule	PeriodicSchedule	The schedule for the periodic swap payments.
holidayCalendars	[Text]	The identifiers of the holiday calendars to be used for the swap payment schedule.
calendarDataProvider	Party	The reference data provider to use for the holiday calendar.
dayCountConvention	DayCountConventionEnum	The day count convention used to calculate day count fractions. For example: Act360.
baseCurrency	InstrumentKey	The base currency of the swap. For example, in the case of USD this should be a USD cash instrument.
foreignCurrency	InstrumentKey	The foreign currency of the swap. For example, in case of EUR this should be a EUR cash instrument.
fxRate	Decimal	The fx rate used to convert from the base currency principal amount to the foreign currency principal amount.
lastEventTimestamp	Time	(Market) time of the last recorded lifecycle event. If no event has occurred yet, the time of creation should be used.

instance [Eq](#) [CurrencySwap](#)

22.3.144 Daml.Finance.Interface.Instrument.Swap.V0.Fpml.FpmlTypes

22.3.144.1 Data Types

data [AdjustableDate](#)

A type for defining a date that shall be subject to adjustment if it would otherwise fall on a day that is not a business day in the specified business centers, together with the convention for adjusting the date.

[AdjustableDate](#)

Field	Type	Description
unadjustedDate	Date	A date subject to adjustment.
dateAdjustments	Business-DayAdjustments	The business day convention and financial business centers used for adjusting the date if it would otherwise fall on a day that is not a business date in the specified business centers. <code>adjustedDate</code> : Optional IdentifiedDate ^ The date once the adjustment has been performed. (Note that this date may change if the business center holidays change).

instance [Eq AdjustableDate](#)

instance [Show AdjustableDate](#)

data [BusinessCenterTime](#)

A type for defining a time with respect to a business day calendar location. For example, 11:00am London time.

[BusinessCenterTime](#)

Field	Type	Description
hourMinuteTime	HourMinuteTime	A time specified in hh:mm:ss format where the second component must be '00', e.g., 11am would be represented as 11:00:00.
businessCenter	Text	

instance [Eq BusinessCenterTime](#)

instance [Show BusinessCenterTime](#)

data [BusinessDayAdjustments](#)

A type defining the business day convention and financial business centers used for adjusting any relevant date if it would otherwise fall on a day that is not a business day in the specified business centers.

[BusinessDayAdjustments](#)

Field	Type	Description
businessDayConvention	Business-DayConventionEnum	The convention for adjusting a date if it would otherwise fall on a day that is not a business day.
businessCenters	[Text]	

instance [Eq BusinessDayAdjustments](#)

instance [Show BusinessDayAdjustments](#)

data [Calculation](#)

The parameters used in the calculation of fixed or floating rate period amounts.

[Calculation](#)

Field	Type	Description
notionalSchedule-Value	NotionalSchedule-Value	
rateTypeValue	RateType-Value	
dayCountFraction	DayCount-Conventio-nEnum	
compounding-MethodEnum	OptionalCompound-ingMethodE-num	

instance [Eq Calculation](#)

instance [Show Calculation](#)

data [CalculationPeriodAmount](#)

The calculation period amount parameters.

[CalculationPeriodAmount](#)

Field	Type	Description
calculation	Calculation	

instance [Eq CalculationPeriodAmount](#)

instance [Show CalculationPeriodAmount](#)

data [CalculationPeriodDates](#)

The calculation periods dates schedule.

[CalculationPeriodDates](#)

Field	Type	Description
id	Text	
effectiveDate	Adjustable-Date	
terminationDate	Adjustable-Date	
calculationPeriod-DatesAdjustments	Calculation-PeriodDate-sAdjust-ments	
firstPeriodStart-Date	Optional Adjustable-Date	
firstRegularPeriodStartDate	Optional Date	
lastRegularPeriodEndDate	Optional Date	
calculationPeriod-Frequency	Calculation-PeriodFre-quency	

instance [Eq CalculationPeriodDates](#)

instance [Show CalculationPeriodDates](#)

data [CalculationPeriodDatesAdjustments](#)

The business day convention to apply to each calculation period end date if it would otherwise fall on a day that is not a business day in the specified financial business centers.

[CalculationPeriodDatesAdjustments](#)

Field	Type	Description
businessDayConvention	Business-DayConventionEnum	
businessCenters	[Text]	

instance [Eq CalculationPeriodDatesAdjustments](#)

instance [Show CalculationPeriodDatesAdjustments](#)

data [CalculationPeriodFrequency](#)

A type defining the frequency at which calculation period end dates occur within the regular part of the calculation period schedule and thier roll date convention. In case the calculation frequency is of value T (term), the period is defined by the swap\swapStream\calculationPeriodDates\effectiveDate and the swap\swapStream\calculationPeriodDates\terminationDate.

[CalculationPeriodFrequency](#)

Field	Type	Description
periodMultiplier	Int	A time period multiplier, e.g., 1, 2 or 3 etc. If the period value is T (Term) then periodMultiplier must contain the value 1.
period	PeriodExtendedEnum	A time period, e.g., a day, week, month, year or term of the stream.
rollConvention	RollConventionEnum	Used in conjunction with a frequency and the regular period start date of a calculation period, determines each calculation period end date within the regular part of a calculation period schedule.

instance [Eq CalculationPeriodFrequency](#)

instance [Show CalculationPeriodFrequency](#)

data [CompoundingMethodEnum](#)

The compounding calculation method

[Flat](#)

Flat compounding. Compounding excludes the spread. Note that the first compounding period has its interest calculated including any spread then subsequent periods compound this at a rate excluding the spread.

[NoCompounding](#)

No compounding is to be applied.

[Straight](#)

Straight compounding. Compounding includes the spread.

[SpreadExclusive](#)

Spread Exclusive compounding.

instance [Eq CompoundingMethodEnum](#)

instance [Show CompoundingMethodEnum](#)

data [DateOffset](#)

A type defining an offset used in calculating a date when this date is defined in reference to another date through a date offset. The type includes the convention for adjusting the date and an optional sequence element to indicate the order in a sequence of multiple date offsets.

[DateOffset](#)

Field	Type	Description
periodMultiplier	Int	A time period multiplier, e.g. 1, 2 or 3 etc. A negative value can be used when specifying an offset relative to another date, e.g. -2 days.
period	PeriodEnum	A time period, e.g. a day, week, month or year of the stream. If the periodMultiplier value is 0 (zero) then period must contain the value D (day).
dayType	Optional DayTypeEnum	In the case of an offset specified as a number of days, this element defines whether consideration is given as to whether a day is a good business day or not. If a day type of business days is specified then non-business days are ignored when calculating the offset. The financial business centers to use for determination of business days are implied by the context in which this element is used. This element must only be included when the offset is specified as a number of days. If the offset is zero days then the dayType element should not be included.

instance [Eq DateOffset](#)

instance [Show DateOffset](#)

data [DateRelativeToEnum](#)

The specification of whether payments/resets occur relative to the first or last day of a calculation period.

[CalculationPeriodStartDate](#)

Payments/Resets will occur relative to the first day of each calculation period.

[CalculationPeriodEndDate](#)

Payments/Resets will occur relative to the last day of each calculation period.

instance [Eq DateRelativeToEnum](#)

instance [Show DateRelativeToEnum](#)

data [DayTypeEnum](#)

A day type classification used in counting the number of days between two dates.

[Business](#)

When calculating the number of days between two dates the count includes only business days.

[Calendar](#)

When calculating the number of days between two dates the count includes all calendar days.

[CommodityBusiness](#)

When calculating the number of days between two dates the count includes only commodity business days.

[CurrencyBusiness](#)

When calculating the number of days between two dates the count includes only currency business days.

[ExchangeBusiness](#)

When calculating the number of days between two dates the count includes only stock exchange business days.

[ScheduledTradingDay](#)

When calculating the number of days between two dates the count includes only scheduled trading days.

instance [Eq DayTypeEnum](#)

instance [Show DayTypeEnum](#)

data [FixedRateSchedule](#)

Specify the fixed rate

[FixedRateSchedule](#)

Field	Type	Description
initialValue	Decimal	The initial rate or amount, as the case may be. An initial rate of 5% would be represented as 0.05.
step	[Step]	The schedule of step date and value pairs. On each step date the associated step value becomes effective. A list of steps may be ordered in the document by ascending step date. An FpML document containing an unordered list of steps is still regarded as a conformant document. type_ : Optional SpreadSchedule-Type

instance [Eq FixedRateSchedule](#)

instance [Show FixedRateSchedule](#)

data [FixingDates](#)

Specifies the fixing date relative to the reset date in terms of a business days offset and an associated set of financial business centers.

[FixingDates](#)

Field	Type	Description
periodMultiplier	Int	
period	PeriodEnum	
dayType	Optional DayType- Enum	
businessDayCon- vention	Business- DayConven- tionEnum	
businessCenters	[Text]	

instance [Eq FixingDates](#)

instance [Show FixingDates](#)

data [FloatingRateCalculation](#)

A type defining the floating rate and definitions relating to the calculation of floating rate amounts.

[FloatingRateCalculation](#)

Field	Type	Description
floatingRateIndex	Text	
indexTenor	Optional Period	The ISDA Designated Maturity, i.e., the tenor of the floating rate. <code>floatingRateMultiplierSchedule</code> : Optional Schedule ^ A rate multiplier or multiplier schedule to apply to the floating rate. A multiplier schedule is expressed as explicit multipliers and dates. In the case of a schedule, the step dates may be subject to adjustment in accordance with any adjustments specified in the <code>calculationPeriodDatesAdjustments</code> . The multiplier can be a positive or negative decimal. This element should only be included if the multiplier is not equal to 1 (one) for the term of the stream.
spreadSchedule	[Spread-Schedule]	The ISDA Spread or a Spread schedule expressed as explicit spreads and dates. In the case of a schedule, the step dates may be subject to adjustment in accordance with any adjustments specified in <code>calculationPeriodDatesAdjustments</code> . The spread is a per annum rate, expressed as a decimal. For purposes of determining a calculation period amount, if positive the spread will be added to the floating rate and if negative the spread will be subtracted from the floating rate. A positive 10 basis point (0.1%) spread would be represented as 0.001. <code>rateTreatment</code> : Optional <code>RateTreatmentEnum</code> ^ The specification of any rate conversion which needs to be applied to the observed rate before being used in any calculations. The two common conversions are for securities quoted on a bank discount basis which will need to be converted to either a Money Market Yield or Bond Equivalent Yield. See the Annex to the 2000 ISDA Definitions, Section 7.3. Certain General Definitions Relating to Floating Rate Options, paragraphs (g) and (h) for definitions of these terms. <code>capRateSchedule</code> : [StrikeSchedule] ^ The cap rate or cap rate schedule, if any, which applies to the floating rate. The cap rate (strike) is only required where the floating rate on a swap stream is capped at a certain level. A cap rate schedule is expressed as explicit cap rates and dates and the step dates may be subject to adjustment in accordance with any adjustments specified in <code>calculationPeriodDatesAdjustments</code> . The cap rate is

instance [Eq FloatingRateCalculation](#)

instance [Show FloatingRateCalculation](#)

data [FxLinkedNotionalSchedule](#)

The notional amount or notional amount schedule (FX linked).

[FxLinkedNotionalSchedule](#)

Field	Type	Description
constantNotionalScheduleReference	Text	
initialValue	Optional Decimal	
varyingNotionalCurrency	Text	
varyingNotionalFixingDates	FixingDates	
fxSpotRateSource	FxSpotRateSource	

instance [Eq FxLinkedNotionalSchedule](#)

instance [Show FxLinkedNotionalSchedule](#)

data [FxSpotRateSource](#)

A type defining the rate source and fixing time for an fx rate.

[FxSpotRateSource](#)

Field	Type	Description
primaryRateSource	InformationSource	The primary source for where the rate observation will occur. Will typically be either a page or a reference bank published rate. secondaryRateSource : Optional InformationSource ^ An alternative, or secondary, source for where the rate observation will occur. Will typically be either a page or a reference bank published rate.
fixingTime	Optional BusinessCenterTime	The time at which the spot currency exchange rate will be observed. It is specified as a time in a business day calendar location, e.g., 11:00am London time.

instance [Eq FxSpotRateSource](#)

instance [Show FxSpotRateSource](#)

type [HourMinuteTime](#) = [Text](#)

A type defining a time specified in hh:mm:ss format where the second component must be '00', e.g., 11am would be represented as 11:00:00.

data [InformationSource](#)

A type defining the source for a piece of information (e.g. a rate refix or an fx fixing).

[InformationSource](#)

Field	Type	Description
rateSource	Text	An information source for obtaining a market rate. For example, Bloomberg, Reuters, Telerate etc. rateSourcePage : Optional RateSourcePage
rateSourcePage	Text	A specific page for the rate source for obtaining a market rate. rateSourcePage-Heading : Optional String ^ The heading for the rate source on a given rate source page.

instance [Eq](#) [InformationSource](#)

instance [Show](#) [InformationSource](#)

data [NotionalSchedule](#)

The notional amount or notional amount schedule.

[NotionalSchedule](#)

Field	Type	Description
id	Text	
notionalStep-Schedule	Notional-StepSchedule	

instance [Eq](#) [NotionalSchedule](#)

instance [Show](#) [NotionalSchedule](#)

data [NotionalScheduleValue](#)

Specifies how the notional schedule is defined: either regular or fx linked.

[NotionalSchedule_Regular](#) [NotionalSchedule](#)

Regular notional schedule.

[NotionalSchedule_FxLinked](#) [FxLinkedNotionalSchedule](#)

FX linked notional schedule.

instance [Eq](#) [NotionalScheduleValue](#)

instance [Show](#) [NotionalScheduleValue](#)

data [NotionalStepSchedule](#)

The notional amount or notional amount schedule expressed as explicit outstanding notional amounts and dates.

[NotionalStepSchedule](#)

Field	Type	Description
initialValue	Decimal	
step	[Step]	
currency	Text	

instance [Eq NotionalStepSchedule](#)

instance [Show NotionalStepSchedule](#)

data [PaymentDates](#)

The payment dates schedule.

[PaymentDates](#)

Field	Type	Description
calculationPeriod-DatesReference	Text	
paymentFrequency	PaymentFrequency	
firstPaymentDate	Optional Date	
lastRegularPaymentDate	Optional Date	
payRelativeTo	DateRelativeToEnum	
paymentDaysOffset	Optional DateOffset	
paymentDatesAdjustments	Business-DayAdjustments	

instance [Eq PaymentDates](#)

instance [Show PaymentDates](#)

data [PaymentFrequency](#)

The frequency at which regular payment dates occur. If the payment frequency is equal to the frequency defined in the calculation period dates component then one calculation period contributes to each payment amount. If the payment frequency is less frequent than the frequency defined in the calculation period dates component then more than one calculation period will contribute to the payment amount. A payment frequency more frequent than the calculation period frequency or one that is not a multiple of the calculation period frequency is invalid. If the payment frequency is of value T (term), the period is defined by the swap\swapStream\calculationPeriodDates\effectiveDate and the swap\swapStream\calculationPeriodDates\terminationDate.

PaymentFrequency

Field	Type	Description
periodMultiplier	Int	
period	PeriodExtendedEnum	

instance [Eq](#) *PaymentFrequency*

instance [Show](#) *PaymentFrequency*

data [PeriodExtendedEnum](#)

The period of a schedule, for example the calculation schedule.

[Regular](#) [PeriodEnum](#)

[T](#)

instance [Eq](#) *PeriodExtendedEnum*

instance [Show](#) *PeriodExtendedEnum*

data [PrincipalExchanges](#)

A type defining which principal exchanges occur for the stream.

[PrincipalExchanges](#)

Field	Type	Description
initialExchange	Bool	A true/false flag to indicate whether there is an initial exchange of principal on the effective date.
finalExchange	Bool	A true/false flag to indicate whether there is a final exchange of principal on the termination date.
intermediateExchange	Bool	A true/false flag to indicate whether there are intermediate or interim exchanges of principal during the term of the swap.

instance [Eq](#) *PrincipalExchanges*

instance [Show](#) *PrincipalExchanges*

data [RateTypeValue](#)

Specifies whether the swapStream has a fixed or a floating rate.

[RateType_Fixed](#) [FixedRateSchedule](#)

Fixed rate.

[RateType_Floating](#) [FloatingRateCalculation](#)

Floating rate.

instance [Eq RateTypeValue](#)

instance [Show RateTypeValue](#)

data [ResetDates](#)

The reset dates schedule. This only applies for a floating rate stream.

[ResetDates](#)

Field	Type	Description
calculationPeriod-DatesReference	Text	
resetRelativeTo	DateRelativeToEnum	
fixingDates	FixingDates	
resetFrequency	ResetFrequency	
resetDatesAdjustments	ResetDatesAdjustments	

instance [Eq ResetDates](#)

instance [Show ResetDates](#)

data [ResetDatesAdjustments](#)

The business day convention to apply to each reset date if it would otherwise fall on a day that is not a business day in the specified financial business centers.

[ResetDatesAdjustments](#)

Field	Type	Description
businessDayConvention	BusinessDayConventionEnum	
businessCenters	[Text]	

instance [Eq ResetDatesAdjustments](#)

instance [Show ResetDatesAdjustments](#)

data [ResetFrequency](#)

The frequency at which reset dates occur.

[ResetFrequency](#)

Field	Type	Description
periodMultiplier	Int	
period	PeriodExtendedEnum	

instance [Eq ResetFrequency](#)

instance [Show ResetFrequency](#)

data [Rounding](#)

A type defining a rounding direction and precision to be used in the rounding of a rate.

[Rounding](#)

Field	Type	Description
roundingDirection	RoundingDirectionEnum	Specifies the rounding direction.
precision	Int	Specifies the rounding precision in terms of a number of decimal places. Note how a percentage rate rounding of 5 decimal places is expressed as a rounding precision of 7 in the FpML document since the percentage is expressed as a decimal, e.g. 9.876543% (or 0.09876543) being rounded to the nearest 5 decimal places is 9.87654% (or 0.0987654).

instance [Eq Rounding](#)

instance [Show Rounding](#)

data [RoundingDirectionEnum](#)

The method of rounding a fractional number.

[Up](#)

A fractional number will be rounded up to the specified number of decimal places (the precision). For example, 5.21 and 5.25 rounded up to 1 decimal place are 5.3 and 5.3 respectively.

[Down](#)

A fractional number will be rounded down to the specified number of decimal places (the precision). For example, 5.29 and 5.25 rounded down to 1 decimal place are 5.2 and 5.2 respectively.

[Nearest](#)

A fractional number will be rounded either up or down to the specified number of decimal places (the precision) depending on its value. For example, 5.24 would be rounded down to 5.2 and 5.25 would be rounded up to 5.3 if a precision of 1 decimal place were specified.

instance [Eq RoundingDirectionEnum](#)

instance [Show RoundingDirectionEnum](#)

data [SpreadSchedule](#)

Adds an optional spread type element to the Schedule to identify a long or short spread value.

[SpreadSchedule](#)

Field	Type	Description
initialValue	Decimal	The initial rate or amount, as the case may be. An initial rate of 5% would be represented as 0.05. step : [Step] ^ The schedule of step date and value pairs. On each step date the associated step value becomes effective. A list of steps may be ordered in the document by ascending step date. An FpML document containing an unordered list of steps is still regarded as a conformant document. type_ : Optional SpreadSchedule-Type

instance [Eq SpreadSchedule](#)

instance [Show SpreadSchedule](#)

data [Step](#)

The schedule of step date and non-negative value pairs. On each step date the associated step value becomes effective. A list of steps may be ordered in the document by ascending step date. An FpML document containing an unordered list of steps is still regarded as a conformant document.

[Step](#)

Field	Type	Description
stepDate	Date	
stepValue	Decimal	

instance [Eq Step](#)

instance [Show Step](#)

data [StubCalculationPeriodAmount](#)

The stub calculation period amount parameters. This element must only be included if there is an initial or final stub calculation period. Even then, it must only be included if either the stub references a different floating rate tenor to the regular calculation periods, or if the stub is calculated as a linear interpolation of two different floating rate tenors, or if a specific stub rate or stub amount has been negotiated.

[StubCalculationPeriodAmount](#)

Field	Type	Description
calculationPeriod-DatesReference	Text	
initialStub	Optional StubValue	
finalStub	Optional StubValue	

instance [Eq StubCalculationPeriodAmount](#)

instance [Show StubCalculationPeriodAmount](#)

data [StubFloatingRate](#)

The rates to be applied to the initial or final stub may be the linear interpolation of two different rates.

[StubFloatingRate](#)

Field	Type	Description
floatingRateIndex	Text	
indexTenor	Optional Period	

instance [Eq StubFloatingRate](#)

instance [Show StubFloatingRate](#)

data [StubValue](#)

Specifies how the stub amount is calculated. A single floating rate tenor different to that used for the regular part of the calculation periods schedule may be specified, or two floating tenors may be specified. If two floating rate tenors are specified then Linear Interpolation (in accordance with the 2000 ISDA Definitions, Section 8.3. Interpolation) is assumed to apply. Alternatively, an actual known stub rate or stub amount may be specified.

[StubValue_FloatingRate](#) [[StubFloatingRate](#)]

The rates to be applied to the initial or final stub may be the linear interpolation of two different rates. While the majority of the time, the rate indices will be the same as that specified in the stream and only the tenor itself will be different, it is possible to specify two different rates. For example, a 2 month stub period may use the linear interpolation of a 1 month and 3 month rate. The different rates would be specified in this component. Note that a maximum of two rates can be specified. If a stub period uses the same floating rate index, including tenor, as the regular calculation periods then this should not be specified again within this component, i.e., the stub calculation period amount component may not need to be specified even if there is an initial or final stub period. If a stub period uses a different floating rate index compared to the regular calculation periods then this should be specified within this component. If specified here, they are likely to have id attributes, allowing them to be referenced from within the cashflows component.

StubValue_StubRate Decimal

An actual rate to apply for the initial or final stub period may have been agreed between the principal parties (in a similar way to how an initial rate may have been agreed for the first regular period). If an actual stub rate has been agreed then it would be included in this component. It will be a per annum rate, expressed as a decimal. A stub rate of 5% would be represented as 0.05. | StubValue_StubAmount Money ^ An actual amount to apply for the initial or final stub period may have been agreed between the two parties. If an actual stub amount has been agreed then it would be included in this component.

instance [Eq StubValue](#)

instance [Show StubValue](#)

data [SwapStream](#)

The swap streams, describing each leg of the swap.

[SwapStream](#)

Field	Type	Description
payerPartyReference	Text	
receiverPartyReference	Text	
calculationPeriodDates	CalculationPeriodDates	
paymentDates	PaymentDates	
resetDates	Optional ResetDates	
calculationPeriodAmount	CalculationPeriodAmount	
stubCalculationPeriodAmount	Optional StubCalculationPeriodAmount	
principalExchanges	Optional PrincipalExchanges

22.3.153 Daml.Finance.Interface.Instrument.Types.V2.FloatingRate

22.3.153.1 Data Types

data [DateRelativeToEnum](#)

The specification of whether payments/resets occur relative to the first or last day of a calculation period.

[CalculationPeriodStartDate](#)

Payments/Resets will occur relative to the first day of each calculation period.

[CalculationPeriodEndDate](#)

Payments/Resets will occur relative to the last day of each calculation period.

instance [Eq](#) [DateRelativeToEnum](#)

instance [Show](#) [DateRelativeToEnum](#)

type [FixingDates](#) = [DateOffset](#)

data [FloatingRate](#)

Specifies the data required for a floating rate coupon.

[FloatingRate](#)

Field	Type	Description
referenceRateId	Text	The identifier of the reference rate to be used for the coupon, e.g. Libor-3M.
referenceRateType	ReferenceRateTypeEnum	The type of reference rate, which defines how the reference rate is calculated.
fixingDates	FixingDates	Specifies the fixing dates as an offset of the calculation date, e.g. -2 business days.

instance [Eq](#) [FloatingRate](#)

instance [Show](#) [FloatingRate](#)

data [ReferenceRateTypeEnum](#)

The type of reference rate, which defines how the reference rate is calculated.

[SingleFixing](#) [DateRelativeToEnum](#)

The reference rate is fixed on one observation date. This is usually the case for Libor and similar reference rates. A [DateRelativeToEnum](#) is required to indicate whether the reference rate will reset relative to the first or the last day of the calculation period.

[CompoundedIndex](#) [DayCountConventionEnum](#)

The reference rate is a regularly (e.g. daily) compounded reference rate, e.g. compounded SOFR, calculated via an index that is continuously compounded since a specified start date. This enables efficient calculation using only the index

values at the start and at the end of the calculation period: `SOFR_INDEX_END / SOFR_INDEX_START - 1`, as described here: https://www.newyorkfed.org/markets/reference-rates/additional-information-about-reference-rates#tgr_bgcr_sofr_calculation_. The day count convention used for the index calculation (by the index provider) is also required. For example, in the case of SOFR this is Act360, which is implied by the 360/dc factor in the formula in the "Calculation Methodology for the SOFR Averages and Index" section in the link above.

instance [Eq ReferenceRateTypeEnum](#)

instance [Show ReferenceRateTypeEnum](#)

22.3.154 Daml.Finance.Interface.Lifecycle.V4.Effect

22.3.154.1 Interfaces

interface [Effect](#)

Interface for contracts exposing effects of lifecycling processes.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Calculate](#)

Given an instrument quantity of the target instrument, it calculates the instrument quantities to settle.

Controller: actor

Returns: [CalculationResult](#)

Field	Type	Description
actor	Party	The flexible controller of the choice.
quantity	InstrumentQuantity	The quantity being targeted.

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Choice [SetProviders](#)

Set the provider of the effect.

Controller: (DA.Internal.Record.getField @"providers" (view this)), newProviders

Returns: [ContractId Effect](#)

Field	Type	Description
newProviders	Parties	The new provider.

Method calculate : [Calculate](#) -> [ContractId Effect](#) -> [Update CalculationResult](#)

Implementation of the `Calculate` choice.

Method `setProviders` : `SetProviders -> Update (ContractId Effect)`

Implementation of the `SetProviders` choice.

22.3.154.2 Data Types

data `CalculationResult`

Data type encapsulating the effect's calculation result.

`CalculationResult`

Field	Type	Description
consumed	<code>[InstrumentQuantity]</code>	Consumed quantities.
produced	<code>[InstrumentQuantity]</code>	Produced quantities.

instance `Eq CalculationResult`

instance `Show CalculationResult`

instance `HasMethod Effect "calculate" (Calculate -> ContractId Effect -> Update CalculationResult)`

type `I = Effect`

Type synonym for `Effect`.

instance `HasMethod Election "apply" (ContractId Election -> Apply -> Update (Optional InstrumentKey, [ContractId I]))`

instance `HasMethod Exercisable "applyElection" (ApplyElection -> Update (Optional InstrumentKey, [ContractId I]))`

instance `HasMethod Lifecycle "evolve" (Evolve -> Update (Optional InstrumentKey, [ContractId I]))`

type `V = View`

Type synonym for `View`.

instance `HasFromAnyView Effect V`

data `View`

View for `Effect`.

`View`

Field	Type	Description
providers	Parties	The parties providing the claim processing.
targetInstrument	InstrumentKey	The target instrument. A holding on this instrument is required to claim the effect. For example, in the case of a swap instrument, this would be the original instrument version before lifecycling, that contains the current swap payment.
producedInstrument	Optional InstrumentKey	The produced instrument, if it exists. For example, in the case of a swap instrument, this would be the new instrument version after lifecycling, that does not contain the current swap payment. If there are no more claims remaining after the current lifecycling, this would be None.
id	Id	A textual identifier.
description	Text	A human readable description of the Effect.
settlementTime	Optional Time	The effect's settlement time (if any).
otherConsumed	[InstrumentQuantity]	Consumed quantities (in addition to the target instrument). For example, in the case of a fix vs floating rate swap, this could be a 2.5% fix payment.
otherProduced	[InstrumentQuantity]	Produced quantities (in addition to the produced instrument). For example, in the case of a fix vs floating rate swap, this could be a 3M Euribor floating payment.

instance [Eq View](#)

instance [Show View](#)

22.3.155 Daml.Finance.Interface.Lifecycle.V4.Election

22.3.155.1 Interfaces

interface [Election](#)

Interface implemented by templates that represents a claim-based election. This interface requires the `Event` interface implementation.

viewtype [V](#)

Choice [Apply](#)

Applies the election to the instrument, returning the new instrument as well as the corresponding effects. The election is archived as part of this choice.

Controller: (DA.Internal.Record.getField @"provider" (view this))

Returns: ([Optional InstrumentKey](#), [[ContractId](#)])

Field	Type	Description
observableCids	[ContractId]	Set of observables.
exercisableCid	ContractId Exercisable	The contract that is used to apply an election to the instrument.

Choice Archive

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Method `apply` : [ContractId Election](#) -> [Apply](#) -> [Update](#) ([Optional InstrumentKey](#), [[ContractId](#)])

Implementation of the `Apply` choice.

interface [Exercisable](#)

Interface implemented by instruments that admit (claim-based) elections.

viewtype [ExercisableView](#)

Choice [ApplyElection](#)

Applies an election to the instrument.

Controller: (DA.Internal.Record.getField @"lifecycler" (view this))

Returns: ([Optional InstrumentKey](#), [[ContractId](#)])

Field	Type	Description
electionCid	ContractId Election	The election.
observableCids	[ContractId]	Set of observables.

Choice Archive

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Exercisable_GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [ExercisableView](#)

Field	Type	Description

<code>viewer</code>	Party	The party retrieving the view.

22.3.159.2 Data Types

type `I` = [Event](#)

Type synonym for `Event`.

type `V` = [View](#)

Type synonym for `View`.

instance [HasFromAnyView Event V](#)

data [View](#)

View for `Event`.

[View](#)

Field	Type	Description
<code>effectiveTime</code>	Time	Time on which the replacement is effected.
<code>targetInstrument</code>	InstrumentKey	Instrument the replacement event applies to.
<code>perUnitReplacement</code>	[InstrumentQuantity]	Instrument quantities the target instrument is replaced with.

instance [Eq View](#)

instance [Show View](#)

22.3.160 `Daml.Finance.Interface.Lifecycle.V4.Event.Time`

22.3.160.1 Interfaces

interface [Event](#)

Event interface for events that signal the passing of (business) time.

viewtype [V](#)

Choice `Archive`

Controller: Signatories of implementing template

Returns: `()`

(no fields)

Choice [GetView](#)

Retrieves the event view. The event's time can be retrieved from the generic `Event` interface.

Controller: `viewer`

Returns: [View](#)

Field	Type	Description
<code>viewer</code>	Party	The party retrieving the view.

Method `advance` : [ContractId Time](#) -> [Advance](#) -> [Update](#) ([ContractId Time](#), [ContractId Event](#))

Implementation of the `Advance` choice.

Method `rewind` : [ContractId Time](#) -> [Rewind](#) -> [Update](#) ([ContractId Time](#), [ContractId Event](#))

Implementation of the `Rewind` choice.

22.3.160.2 Data Types

type *I* = *Event*

Type synonym for *Event*.

type *V* = *View*

Type synonym for *View*.

22.3.161 Daml.Finance.Interface.Lifecycle.V4.Observable.NumericObservable

This module defines an interface for a *NumericObservable*, which is used to inspect time-dependent numerical values.

22.3.161.1 Interfaces

interface *NumericObservable*

An interface to inspect some (time-dependent) numerical values (e.g. a stock price or an interest rate fixing) required when processing a lifecycle rule.

viewtype *V*

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party retrieving the view.

Choice *Observe*

Observe the *Observable*.

Controller: actors

Returns: *Decimal*

Field	Type	Description
actors	<i>Parties</i>	Parties calling this 'Observe' choice.
t	<i>Time</i>	Time at which the value is observed.

Method observe : [Time](#) -> [Update Decimal](#)

Implementation of the `Observe` choice.

22.3.161.2 Data Types

type [I](#) = [NumericObservable](#)

Type synonym for `Observable`.

type [V](#) = [View](#)

Type synonym for `View`.

instance [HasFromAnyView](#) [NumericObservable](#) [V](#)

data [View](#)

View for `Observable`.

[View](#)

Field	Type	Description
provider	Party	Party providing the observations.
id	Id	Textual reference to the observable.

instance [Eq](#) [View](#)

instance [Show](#) [View](#)

22.3.161.3 Functions

observe : [NumericObservable](#) -> [Time](#) -> [Update Decimal](#)

22.3.162 [Daml.Finance.Interface.Lifecycle.V4.Observable.TimeObservable](#)

This module defines an interface for a `TimeObservable`, which is implemented by templates exposing time information.

22.3.162.1 Interfaces

interface [TimeObservable](#)

An interface to inspect a time value.

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetTime](#)

Retrieves the current time.

Controller: actors

Returns: [Time](#)

Field	Type	Description
actors	Parties	The party retrieving the current time.

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Method [getTime](#) : [Update Time](#)Implementation of the `GetTime` choice.

22.3.163 Daml.Finance.Interface.Lifecycle.V4.Rule.Claim

22.3.163.1 Interfaces

interface [Claim](#)Interface for contracts that allow holders to claim an `Effect` and generate `SettlementInstruction`s.**viewtype** [V](#)

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *ClaimEffect*

Claim an effect and generate corresponding settlement instructions.

Controller: claimer

Returns: *ClaimResult*

Field	Type	Description
claimer	<i>Party</i>	The party claiming the effect.
holdingCids	[<i>ContractId</i>]	The holdings to process.
effectCid	<i>ContractId</i> /	The effect to process.
batchId	<i>Id</i>	Identifier used for the generated settlement batch.

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party retrieving the view.

Method *claimEffect* : *ClaimEffect* -> *Update ClaimResult*Implementation of the *ClaimEffect* choice.

22.3.163.2 Data Types

data *ClaimResult*Data type wrapping the results of *Claim*ing an *Effect*.*ClaimResult*

Field	Type	Description
batchCid	<i>ContractId</i> /	Batch used to batch-settle settlement instructions.
instructionCids	[<i>ContractId</i>]	Settlement instructions to settle all effect consequences.

22.3.164 Daml.Finance.Interface.Lifecycle.V4.Rule.Lifecycle

22.3.164.1 Interfaces

interface [Lifecycle](#)

Interface implemented by instruments that can be lifecycled (either by the instrument itself or by a separate rule contract).

viewtype [V](#)

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [Evolve](#)

Process an event. It returns a tuple of the lifecycled instrument (or the original instrument when the former does not exist) and the effects.

Controller: (DA.Internal.Record.getField @"lifecycler" (view this))

Returns: ([Optional InstrumentKey](#), [[ContractId I](#)])

Field	Type	Description
eventCid	ContractId I	The event.
instrument	InstrumentKey	The target instrument.
observableCids	[ContractId I]	Set of numerical time-dependent observables.

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [View](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Method evolve : [Evolve](#) -> [Update](#) ([Optional InstrumentKey](#), [\[ContractId I\]](#))

Implementation of the `Evolve` choice.

22.3.165.1 Interfaces

interface *Batch*

An interface for atomically settling a batch of *Instruction*\s. The corresponding Instructions are referenced by key.

viewtype *V*

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *Cancel*

Cancels the batch.

Controller: actors

Returns: [*ContractId*]

Field	Type	Description
actors	<i>Parties</i>	The parties canceling the batch.

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party retrieving the view.

Choice *Settle*

Settles the batch.

Controller: actors

Returns: [*ContractId*]

Field	Type	Description
actors	<i>Parties</i>	The parties settling the batch.

Method *cancel* : *Cancel* -> *Update* [*ContractId*]

Implementation of the *Cancel* choice.

Method *settle* : *Settle* -> *Update* [*ContractId*]

Implementation of the *Settle* choice.

22.3.165.2 Data Types

type *I* = *Batch*

Type synonym for *Batch*.

22.3.169 Daml.Finance.Interface.Settlement.V4.Types

22.3.169.1 Data Types

data *Allocation*

Describes an allocation of an *Instruction*.

Unallocated

An unallocated instruction.

Pledge (*ContractId I*)

Settle the instruction with the pledged asset.

CreditReceiver

Settle the instruction by crediting the receiver account (where the sender is custodian).

SettleOffledger

Settle the instruction off-ledger.

PassThroughFrom (*AccountKey*, *InstructionKey*)

Settle the instruction with the holding coming from the specified instruction and account.

instance *Eq Allocation*

instance *Show Allocation*

data *Approval*

Describes an approval of an *Instruction*.

Unapproved

An unapproved instruction.

TakeDelivery AccountKey

Take delivery to the specified account.

DebitSender

Debit the sender account with the provided asset (where the receiver is custodian).

SettleOffledgerAcknowledge

Acknowledge settlement of the instruction off-ledger.

PassThroughTo (*AccountKey*, *InstructionKey*)

Take delivery to the specified account. The holding is then immediately allocated to the specified instruction.

instance [Eq Approval](#)

instance [Show Approval](#)

data [InstructionKey](#)

A unique key for Instructions.

instance [HasMaintainer](#) Reference [HoldingFactoryKey](#)

instance [HasToAnyContractKey](#) Reference [HoldingFactoryKey](#)

data [HoldingStandard](#)

The [HoldingStandard](#) data type categorizes holdings into four distinct classes, each defined by the combination of holding interfaces they implement: [Transferable.I](#), [Fungible.I](#), and [Holding.I](#). Notably, [Transferable.I](#) and [Fungible.I](#) both require the implementation of the [Holding.I](#) interface. Please also note that, in this context, "Transferable.I" refers to the capability of a holding to be transferred between parties (e.g., from Alice to Bob) through a single custodian. Additionally, it is important to highlight that all classes of holdings can be credited and debited, and thereby effectively settled.

[TransferableFungible](#)

Represents the class of holdings which implement `Fungible.I` and `Transferable.I`, and by extension `Holding.I`. Holdings in this class are both interchangeable (fungible) and can be transferred between parties (such as Alice to Bob) via a custodian.

Transferable

Represents the class of holdings which implement `Transferable.I` and, by extension, `Holding.I`, but not `Fungible.I`. This class pertains to assets that can be transferred between parties through a custodian, but are not interchangeable.

Fungible

Represents the class of holdings which implement `Fungible.I` and, by extension, `Holding.I`, but not `Transferable.I`. These holdings are interchangeable, suitable for scenarios where asset fungibility is crucial, but do not have the transfer capability between parties via a custodian.

BaseHolding

Represents the class of holdings which implement only `Holding.I` and neither `Transferable.I` nor `Fungible.I`. This class encompasses basic holdings without the functionalities of custodian-based transferability or fungibility.

22.3.173 Daml.Finance.Interface.Types.Date.V3.DateOffset

22.3.173.1 Data Types

data [DateOffset](#)

A date offset type that can be used e.g. to specify a rate fixing date relative to the reset date in terms of a business days offset and an associated set of financial business centers.

[DateOffset](#)

Field	Type	Description
period	PeriodEnum	The unit of the date offset, e.g. D means that the date offset is specified in days.
periodMultiplier	Int	The number of days (if period is D) before or after the base date the fixing is observed.
dayType	Optional DayTypeEnum	Indicate whether the date offset is given in Business days or Calendar days.
businessDayConvention	BusinessDayConventionEnum	Business day convention that describes how a non-business day is adjusted.
businessCenters	[Text]	The identifiers of the holiday calendars to be used for date adjustment (if any).

instance [Eq DateOffset](#)

instance [Show DateOffset](#)

data [DayTypeEnum](#)

A day type classification used in counting the number of days between two dates.

[Business](#)

When calculating the number of days between two dates the count includes only business days.

[Calendar](#)

When calculating the number of days between two dates the count includes all calendar days.

instance [Eq DayTypeEnum](#)

instance [Show DayTypeEnum](#)

22.3.174 Daml.Finance.Interface.Types.Date.V3.DayCount

22.3.174.1 Data Types

data [DayCountConventionEnum](#)

An enum type to specify a day count convention used to calculate day count fractions. For a detailed definition of each convention, we refer to the "Method of Interest Computation Indicator" definitions in the context of the ISO-20022 standard. Where useful, we provide disambiguation comments.

[Act360](#)

Actual 360. In CDM it is called `DayCountFractionEnum_ACT_360`. In ISO20022 it is called A004.

[Act365Fixed](#)

Actual 365 fixed. In CDM it is called *DayCountFractionEnum_ACT_365_FIXED*. In ISO20022 it is called A005.

Act365NL

Actual 365NL (No Leap). It excludes any leap days from the day count in each period (exclusive-inclusive). In ISO20022 it is called A014.

Act365L

Actual 365L. In CDM it is called *DayCountFractionEnum_ACT_365L*. In ISO20022 it is called A009.

ActActAFB

Actual Actual AFB. In CDM it is called *DayCountFractionEnum_ACT_ACT_AFB*. In ISO20022 it is called A010.

ActActISDA

Actual Actual ISDA. In CDM it is called *DayCountFractionEnum_ACT_ACT_ISDA*. In ISO20022 it is called A008.

ActActICMA

Actual Actual ICMA. In CDM it is called *DayCountFractionEnum_ACT_ACT_ICMA* and *DayCountFractionEnum_ACT_ACT_ISMA* (they are identical: <https://www.isda.org/2011/01/07/act-act-icma/>). In ISO20022 it is called A006. Also called ISMA in the 1998 ISDA paper.

Basis1

1/1. In CDM it is called *DayCountFractionEnum__1_1*. Currently not included in ISO20022.

Basis30360

30/360. In CDM it is called *DayCountFractionEnum__30_360*. In ISO20022 it is called A001. Also called 30/360 ISDA or American Basic rule.

Basis30365

30/365. In ISO20022 it is called A002.

Basis30360ICMA

30/360 ICMA. In CDM it is called *DayCountFractionEnum__30E_360*. In ISO20022 it is called A011. Also called Basic Rule. This corresponds to "30E/360" of the 2006 ISDA definitions.

Basis30E360

30E/360. In CDM it is called *DayCountFractionEnum__30E_360_ISDA*. In ISO20022 it is called A007. Also called Eurobond basis. This corresponds to "30E360 (ISDA)" of the 2006 ISDA definitions.

Basis30E2360

30E2/360. In ISO20022 it is called A012. Also called Eurobond basis model 2.

Basis30E3360

30E3/360. Currently not included in CDM. In ISO20022 it is called A013. Also called Eurobond basis model 3.

instance [Eq DayCountConventionEnum](#)

instance [Show DayCountConventionEnum](#)

22.3.175 Daml.Finance.Interface.Types.Date.V3.RollConvention

22.3.175.1 Data Types

data [Period](#)

A data type to define periods.

[Period](#)

Field	Type	Description
period	PeriodEnum	A period, e.g., a day, week, month or year.
periodMultiplier	Int	A period multiplier, e.g., 1, 2 or 3 etc.

instance [Eq Period](#)

instance [Show Period](#)

data [PeriodEnum](#)

An enum type to specify a period, e.g., day or week.

[D](#)

Day

[M](#)

Month

[W](#)

Week

[Y](#)

Year

instance [Eq PeriodEnum](#)

instance [Show PeriodEnum](#)

data [RollConventionEnum](#)

An enum type to specify how to roll dates.

[EOM](#)

Rolls on month end.

[DOM Int](#)

Rolls on the corresponding day of the month.

[*NoRollConvention*](#)

No roll convention is specified. This is for e.g. when date roll is not required (D or W tenors, single-period schedules).

instance [Eq *RollConventionEnum*](#)

instance [Show *RollConventionEnum*](#)

22.3.176 Daml.Finance.Interface.Types.Date.V3.Schedule

22.3.176.1 Data Types

data [*Frequency*](#)

Frequency of a periodic schedule.

[*Frequency*](#)

Field	Type	Description
period	<i>Period</i>	The period (e.g., 1D, 3M, 1Y).
rollConvention	<i>RollConventionEnum</i>	The roll convention.

instance [Eq *Frequency*](#)

instance [Show *Frequency*](#)

data [*PeriodicSchedule*](#)

A periodic schedule.

[*PeriodicSchedule*](#)

Field	Type	Description
effectiveDate	Date	Effective date, i.e., the (unadjusted) start date of the first period.
terminationDate	Date	Termination date, i.e., the (unadjusted) end date of the last period.
firstRegularPeriodStartDate	Optional Date	The (unadjusted) start date of the first regular period (optional).
lastRegularPeriodEndDate	Optional Date	The (unadjusted) end date of the last regular period (optional).
frequency	ScheduleFrequency	The frequency of the periodic schedule.
businessDayAdjustment	BusinessDayAdjustment	The business day adjustment to determine adjusted dates.
effectiveDateBusinessDayAdjustment	Optional BusinessDayAdjustment	The (optional) business day adjustment of the effective date
terminationDateBusinessDayAdjustment	Optional BusinessDayAdjustment	The (optional) business day adjustment of the termination date
stubPeriodType	Optional StubPeriodTypeEnum	An optional stub to define a stub implicitly and not via <code>firstRegularPeriodStartDate</code> or <code>lastRegularPeriodEndDate</code> .

instance [Eq PeriodicSchedule](#)

instance [Show PeriodicSchedule](#)

type [Schedule](#) = [[SchedulePeriod](#)]

A schedule defined by a list of periods.

data [ScheduleFrequency](#)

Frequency of a schedule. It can be specified as a regular frequency or as `SinglePeriod`.

[Periodic Frequency](#)

Periodic frequency (e.g. 1D, 3M, 1Y).

[SinglePeriod](#)

Used for schedules that have exactly one regular period covering their full term (from `effectiveDate` to `terminationDate`).

instance [Eq ScheduleFrequency](#)

instance [Show ScheduleFrequency](#)

data [SchedulePeriod](#)

A single period in a schedule.

[SchedulePeriod](#)

Field	Type	Description
adjustedEndDate	Date	Adjusted end date.
adjustedStartDate	Date	Adjusted start date.
unadjustedEnd-Date	Date	Unadjusted end date.
unadjustedStart-Date	Date	Unadjusted start date.
stubType	Optional StubPeriod-TypeEnum	Indicates whether this period is a stub (and if so, what type of stub it is)

instance [Eq SchedulePeriod](#)

instance [Show SchedulePeriod](#)

data [StubPeriodTypeEnum](#)

An enum type to specify a stub.

[LongFinal](#)

A long (more than one period) final stub.

[LongInitial](#)

A long (more than one period) initial stub.

[ShortFinal](#)

A short (less than one period) final stub.

[ShortInitial](#)

A short (less than one period) initial stub.

instance [Eq StubPeriodTypeEnum](#)

instance [Show StubPeriodTypeEnum](#)

22.3.177 Daml.Finance.Interface.Util.V3.Common

22.3.177.1 Functions

verify : [CanAssert m => Bool -> Text -> m \(\)](#)

Verify is assertMsg with its arguments flipped.

qty : [Decimal -> InstrumentKey -> InstrumentQuantity](#)

Wraps an amount and an instrument key into an instrument quantity.

scale : [Decimal -> InstrumentQuantity -> InstrumentQuantity](#)

Scale quantity by the provided factor.

22.3.178 Daml.Finance.Interface.Util.V3.Disclosure

22.3.178.1 Interfaces

interface *Disclosure*

An interface for managing the visibility of contracts for non-authorizing parties.

viewtype *V*

Choice *AddObservers*

Add a single new observer context to the existing observers.

Controller: disclosers

Returns: *ContractId Disclosure*

Field	Type	Description
disclosers	<i>Parties</i>	Party calling this choice.
observersToAdd	(<i>Text</i> , <i>Parties</i>)	Parties to add as observers to the contract and the corresponding observer context. If the observer context already exists, the new set of parties is added to the old one.

Choice *Archive*

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice *GetView*

Retrieves the interface view.

Controller: viewer

Returns: *View*

Field	Type	Description
viewer	<i>Party</i>	The party retrieving the view.

Choice *RemoveObservers*

Remove observers from a context. None is returned if no update is needed. Parties for a context can be removed if any of the disclosers are part of the observers to be removed or the disclosureControllers.

Controller: disclosers

Returns: *Optional (ContractId Disclosure)*

Field	Type	Description
disclosers	<i>Parties</i>	Parties calling this choice.
observersToRemove	(<i>Text</i> , <i>Parties</i>)	Parties to be removed from the contract observers and the corresponding observer context.

Choice *SetObservers*

Set the observers for a contract.

Controller: disclosers

Returns: *ContractId Disclosure*

Field	Type	Description
disclosers	Parties	Party calling this choice.
newObservers	PartiesMap	Observers to set for this contract. This overrides the existing observers. The parties are mapped by a specific key. The textual key is the "observation context" of the disclosure. This allows processes to add/remove parties for their specific purpose, without affecting others.

Method addObservers : [AddObservers](#) -> [Update \(ContractId Disclosure\)](#)

Implementation of the AddObservers choice.

Method removeObservers : [ContractId Disclosure](#) -> [RemoveObservers](#) -> [Update \(Optional \(ContractId Disclosure\)\)](#)

Implementation of the RemoveObservers choice.

Method setObservers : [SetObservers](#) -> [Update \(ContractId Disclosure\)](#)

Implementation of the SetObservers choice.

22.3.178.2 Data Types

type [I](#) = [Disclosure](#)

Type synonym for [Disclosure](#).

type [V](#) = [View](#)

Type synonym for [View](#).

instance [HasFromAnyView](#) [Disclosure](#) [V](#)

data [View](#)

[View](#) for [Disclosure](#).

[View](#)

Field	Type	Description
disclosureCon- trollers	Parties	Disjunction choice controllers.
observers	PartiesMap	Observers with context. The parties are mapped by a specific key. The textual key is the "observation context" of the disclosure. This allows processes to add/remove parties for their specific purpose, without affecting others.

instance [Eq](#) [View](#)

instance [Show](#) [View](#)

22.3.178.3 Functions

setObservers : [Disclosure](#) -> [SetObservers](#) -> [Update](#) ([ContractId](#) [Disclosure](#))

addObservers : [Disclosure](#) -> [AddObservers](#) -> [Update](#) ([ContractId](#) [Disclosure](#))

removeObservers : [Disclosure](#) -> [ContractId](#) [Disclosure](#) -> [RemoveObservers](#) -> [Update](#) ([Optional](#) ([ContractId](#) [Disclosure](#)))

flattenObservers : [PartiesMap](#) -> [Parties](#)

Flattens observers which use the [PartiesMap](#) into a [Set](#) [Party](#) for usage in template definitions. For example:

```
observer $ flattenObservers observers
```

22.3.179 Daml.Finance.Interface.Util.V3.InterfaceKey

22.3.179.1 Functions

fetchInterfaceByKey : ([HasInterfaceTypeRep](#) i1, [HasInterfaceTypeRep](#) i2, [HasFetchByKey](#) ref k, [HasField](#) "cid" ref ([ContractId](#) i1), [HasFetch](#) i2) => k -> [Update](#) i2
Fetch an interface by key.

22.3.180 Daml.Finance.Interface.Util.V3.Lockable

22.3.180.1 Interfaces

interface [Lockable](#)

An interface for managing locking of contracts. Locking is a mechanism to temporarily encumber contracts by adding third-party lockers as additional signatories.

viewtype [V](#)

Choice [Acquire](#)

Lock a contract.

Controller: ([DA.Internal.Record.getField](#) @"controllers" (view this)), newLockers

Returns: [ContractId](#) [Lockable](#)

Field	Type	Description
newLockers	Parties	Parties which restrain the contract's ability to perform specified actions.
context	Text	Reason for acquiring a lock.
lockType	LockType	Type of lock to acquire.

Choice [Archive](#)

Controller: Signatories of implementing template

Returns: ()

(no fields)

Choice [GetView](#)

Retrieves the interface view.

Controller: viewer

Returns: [V](#)

Field	Type	Description
viewer	Party	The party retrieving the view.

Choice [Release](#)

Unlock a locked contract.

Controller: getLockers this

Returns: [ContractId Lockable](#)

Field	Type	Description
context	Text	

Method acquire : [Acquire](#) -> [Update](#) ([ContractId Lockable](#))

Implementation of the [Acquire](#) choice.

Method release : [Release](#) -> [Update](#) ([ContractId Lockable](#))

Implementation of the [Release](#) choice.

22.3.180.2 Data Types

type [I](#) = [Lockable](#)

Type synonym for [Lockable](#).

data [Lock](#)

Locking details.

[Lock](#)

Field	Type	Description
lockers	Parties	Parties which are locking the contract.
context	Set Text	Context of the lock, explaining why this lock is held by the locking parties. If the lock is reentrant, there may be more than one locking context for the set of lockers.
lockType	LockType	The type of lock applied.

instance [Eq](#) [Lock](#)**instance** [Show](#) [Lock](#)**data** [LockType](#)

Type of lock held.

[Semaphore](#)

A one time only lock.

[Reentrant](#)

A mutual exclusion lock where the same lockers may lock a contract multiple times.

instance [Eq](#) [LockType](#)**instance** [Show](#) [LockType](#)

type *V* = *View*

Type synonym for *View*.

instance *HasFromAnyView Lockable V*

data *View*

View for *Lockable*.

View

Field	Type	Description
lock	<i>Optional Lock</i>	An optional lock, indicating if it is locked or not.
controllers	<i>Parties</i>	All parties whose authorization is required to acquire a lock.

instance *Eq View*

instance *Show View*

22.3.180.3 Functions

acquire : *Lockable* -> *Acquire* -> *Update* (*ContractId Lockable*)

release : *Lockable* -> *Release* -> *Update* (*ContractId Lockable*)

getLockers : *HasToInterface* *t Lockable* => *t* -> *Parties*

Retrieves the lockers of a *Lockable*.

mustNotBeLocked : *HasToInterface* *i Lockable* => *i* -> *Update* ()

Asserts that a lockable is not locked.

22.3.181 Daml.Finance.Lifecycle.V4.Effect

22.3.181.1 Templates

template *Effect*

A contract encoding the consequences of a lifecycle event for one unit of the target instrument.

Signatory: providers

Field	Type	Description
providers	Parties	The effect provider.
id	Id	The effect's identifier.
description	Text	The effect's description.
targetInstrument	InstrumentKey	The target instrument. A holding on this instrument is required to claim the effect. For example, in the case of a swap instrument, this would be the original instrument version before lifecycling, that contains the current swap payment.
producedInstrument	Optional InstrumentKey	The produced instrument, if it exists. For example, in the case of a swap instrument, this would be the new instrument version after lifecycling, that does not contain the current swap payment. If there are no more claims remaining after the current lifecycling, this would be None.
otherConsumed	[InstrumentQuantity]	Consumed quantities (in addition to the target instrument). For example, in the case of a fix vs floating rate swap, this could be a 2.5% fix payment.
otherProduced	[InstrumentQuantity]	Produced quantities (in addition to the produced instrument). For example, in the case of a fix vs floating rate swap, this could be a 3M Euribor floating payment.
settlementTime	Optional Time	The effect's settlement time (if any).
observers	PartiesMap	Observers.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance *I* for [Effect](#)

interface instance *I* for [Effect](#)

22.3.181.2 Data Types

type *T* = [Effect](#)

Type synonym for [Effect](#).

22.3.182 Daml.Finance.Lifecycle.V4.Election

22.3.182.1 Templates

template [Election](#)

An election, such as the exercise of an option.

Signatory: elector, provider

Field	Type	Description
elector	Party	Entity making the election.
counterparty	Party	Faces the <code>elector</code> in the <code>Holding</code> .
provider	Party	The provider of the election is an entity that has the authority to process the election and create a new instrument version.
id	Id	Election identifier.
description	Text	A human readable description of the election.
instrument	InstrumentKey	The instrument to which the election applies.
amount	Decimal	Number of units of instrument to which the election applies.
claim	Text	The tag corresponding to the elected sub-tree.
electorIsOwner	Bool	True if the elector is the owner of a claim, False otherwise.
electionTime	Time	Time at which the election is put forward.
observers	PartiesMap	A set of observers.

Choice Archive

Controller: elector, provider

Returns: ()

(no fields)

interface instance *I* for [Election](#)

interface instance *I* for [Election](#)

interface instance *I* for [Election](#)

template [Factory](#)

Factory template to create an `Election`.

Signatory: provider

Field	Type	Description
provider	Party	The provider of the <code>Factory</code> .
observers	PartiesMap	A set of observers.

Choice Archive

Controller: provider

Returns: ()

(no fields)

interface instance *I* for [Factory](#)

interface instance *I* for [Factory](#)

22.3.182.2 Data Types

type `T` = `Election`

Type synonym for `Election`.

22.3.183 Daml.Finance.Lifecycle.V4.ElectionEffect

22.3.183.1 Templates

template `ElectionEffect`

A contract encoding the consequences of an election for one unit of the target instrument. It needs to be claimed with the right amount and is consumed after claiming.

Signatory: providers

Field	Type	Description
providers	<code>Parties</code>	The effect provider.
custodian	<code>Party</code>	The custodian of the holding put forward for election.
owner	<code>Party</code>	The owner of the holding put forward for election.
id	<code>Id</code>	The effect's identifier.
description	<code>Text</code>	The effect's description.
targetInstrument	<code>InstrumentKey</code>	The target instrument.
producedInstrument	<code>Optional InstrumentKey</code>	The produced instrument, when it exists.
amount	<code>Decimal</code>	The elected amount.
otherConsumed	<code>[InstrumentQuantity]</code>	Consumed quantities (not including the target instrument).
otherProduced	<code>[InstrumentQuantity]</code>	Produced quantities (not including the produced instrument).
settlementTime	<code>Optional Time</code>	The effect's settlement time (if any).
observers	<code>PartiesMap</code>	Observers.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance `I` for `ElectionEffect`

interface instance `I` for `ElectionEffect`

22.3.183.2 Data Types

type *T* = *ElectionEffect*

Type synonym for `ElectionEffect`.

22.3.184 Daml.Finance.Lifecycle.V4.Event.Distribution

22.3.184.1 Templates

template *Event*

Event contract for the distribution of units of an instrument for each unit of a target instrument (e.g. share or cash dividends).

Signatory: providers

Field	Type	Description
providers	<i>Parties</i>	Providers of the distribution event.
id	<i>Id</i>	Event Identifier.
description	<i>Text</i>	Event description.
effectiveTime	<i>Time</i>	Time on which the distribution is effectuated.
targetInstrument	<i>InstrumentKey</i>	Instrument the distribution event applies to.
newInstrument	<i>InstrumentKey</i>	Instrument after the distribution has been claimed.
perUnitDistribution	<i>[InstrumentQuantity]</i>	Distributed quantities per unit held.
observers	<i>Parties</i>	Observers.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance *I* for *Event*

interface instance *I* for *Event*

22.3.184.2 Data Types

type *T* = *Event*

Type synonym for `Event`.

22.3.185 Daml.Finance.Lifecycle.V4.Event.Replacement

22.3.185.1 Templates

template *Event*

Event contract for the replacement of units of an instrument with a basket of other instruments, e.g., a stock merger.

Signatory: providers

Field	Type	Description
providers	Parties	Providers of the distribution event.
id	Id	Event identifier.
description	Text	Event description.
effectiveTime	Time	Time on which the replacement is effectuated.
targetInstrument	InstrumentKey	Instrument the replacement event applies to.
perUnitReplacement	[InstrumentQuantity]	Instrument quantities the target instrument is replaced with.
observers	Parties	Observers.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance *I* for [Event](#)

interface instance *I* for [Event](#)

22.3.185.2 Data Types

type *T* = [Event](#)

Type synonym for [Event](#).

22.3.186 Daml.Finance.Lifecycle.V4.Rule.Claim

22.3.186.1 Templates

template [Rule](#)

Rule contract that allows an actor to claim effects, returning settlement instructions.

Signatory: provider

Field	Type	Description
provider	Party	Provider of the claim rule. Together with the actors of the ClaimEffect choice the authorization requirements to upgrade the holdings being claimed have to be met.
claimers	Parties	Any of the parties can claim an effect.
settlers	Parties	Any of the parties can trigger settlement of the resulting batch.
routeProviderCid	ContractId <i>I</i>	RouteProvider used to discover settlement routes.
settlementFactoryCid	ContractId <i>I</i>	Settlement factory contract used to create a Batch of Instruction s.
netInstructions	Bool	Configure whether netting should be enabled for quantities having the same (instrument, sender, receiver).

Choice Archive

Controller: provider

Returns: ()
(no fields)
interface instance *I* for *Rule*

22.3.186.2 Data Types

type *T* = *Rule*
Type synonym for *Rule*.

22.3.187 Daml.Finance.Lifecycle.V4.Rule.Distribution

22.3.187.1 Templates

template *Rule*

Rule contract that defines the distribution of units of an instrument for each unit of a target instrument (e.g. share or cash dividends).

Signatory: providers

Field	Type	Description
providers	<i>Parties</i>	Providers of the distribution rule.
lifecyclel	<i>Party</i>	Party performing the lifecyclel.
observers	<i>Parties</i>	Observers of the distribution rule.
id	<i>Id</i>	Identifier for the rule contract.
description	<i>Text</i>	Textual description.

Choice Archive
Controller: providers
Returns: ()
(no fields)
interface instance *I* for *Rule*

22.3.187.2 Data Types

type *T* = *Rule*
Type synonym for *Rule*.

22.3.188 Daml.Finance.Lifecycle.V4.Rule.Replacement

22.3.188.1 Templates

template *Rule*

Rule contract that defines the replacement of units of an instrument with a basket of other instruments (e.g. stock merger).

Signatory: providers

Field	Type	Description
providers	Parties	Providers of the replacement rule.
lifecycler	Party	Party performing the lifecycling.
observers	Parties	Observers.
id	Id	Identifier for the rule contract.
description	Text	Textual description.

Choice Archive

Controller: providers

Returns: ()

(no fields)

interface instance *I* for [Rule](#)

22.3.188.2 Data Types

type *T* = [Rule](#)

Type synonym for Rule.

22.3.189 Daml.Finance.Lifecycle.V4.Rule.Util

22.3.189.1 Data Types

data [Pending](#)

Type used to record pending payments.

[Pending](#)

Field	Type	Description
instrument	InstrumentKey	
amount	Decimal	

instance [Eq](#) [Pending](#)

instance [Show](#) [Pending](#)

22.3.189.2 Functions

[mergeConsumedAndProduced](#) : [[InstrumentQuantity](#)] -> [[InstrumentQuantity](#)] -> [[Pending](#)]

Merge consumed and produced instruments into a list of pending settlements. This will only reproduce instrument and quantity, not tag or time.

[splitPending](#) : [[Pending](#)] -> ([[InstrumentQuantity](#)], [[InstrumentQuantity](#)])

Map pending settlements into corresponding instrument quantities and split them into consumed and produced. Pending items with an amount of 0.0 are discarded.

[net](#) : [[Pending](#)] -> [[Pending](#)]

Net pending payments on the same instrument (regardless of tags).

22.3.190 Daml.Finance.Settlement.V4.Batch

22.3.190.1 Templates

template *Batch*

Allows you to atomically settle a set of settlement *Step*.

Signatory: instructor, consenters

Field	Type	Description
<i>instructor</i>	<i>Party</i>	Party instructing settlement (and the creation of the <i>Batch</i>).
<i>consenters</i>	<i>Parties</i>	Parties consenting with the creation of the <i>Batch</i> .
<i>settlers</i>	<i>Parties</i>	Any of the parties can trigger the settlement.
<i>id</i>	<i>Id</i>	<i>Batch</i> identifier.
<i>description</i>	<i>Text</i>	<i>Batch</i> description.
<i>contextId</i>	<i>Optional Id</i>	Identifier to link a batch to a context (e.g. the <i>Effect</i> it originated from).
<i>routedStepsWithInstructionId</i>	<i>[(RoutedStep, Id)]</i>	The settlement <i>RoutedStep</i> \s and the identifiers of the corresponding <i>Instruction</i> \s.
<i>settlementTime</i>	<i>Optional Time</i>	Settlement time (if any).

Choice *Archive*

Controller: instructor, consenters

Returns: ()

(no fields)

interface instance *I* for *Batch*

22.3.190.2 Data Types

type *T* = *Batch*

Type synonym for *Batch*.

22.3.191 Daml.Finance.Settlement.V4.Factory

22.3.191.1 Templates

template *Factory*

Factory template that implements the *Factory* interface. It is used to create a set of settlement *Instruction*\s, and a *Batch* to atomically settle them.

Signatory: provider

Field	Type	Description
<i>provider</i>	<i>Party</i>	Party providing the facility.
<i>observers</i>	<i>Parties</i>	Observers.

Choice Archive
 Controller: provider
 Returns: ()
 (no fields)
interface instance *I* for *Factory*

22.3.192 Daml.Finance.Settlement.V4.Hierarchy

22.3.192.1 Data Types

data *Hierarchy*

Data type that describes a hierarchical account structure among multiple parties for holdings on an instrument.

Hierarchy

Field	Type	Description
rootCustodian	<i>Party</i>	Root custodian of the instrument.
pathsToRootCustodian	<i>[[Party]]</i>	Paths from "leaf" owners to the root custodian of the instrument.

instance *Eq Hierarchy*

instance *Show Hierarchy*

22.3.192.2 Functions

unfoldStep : *Hierarchy* -> *Step* -> *Optional [RoutedStep]*

22.3.193 Daml.Finance.Settlement.V4.Instruction

22.3.193.1 Templates

template *Instruction*

Instruction is used to settle a single settlement *Step*. In order to settle the instruction,
 the sender must allocate a suitable holding
 the receiver must define the receiving account

Signatory: instructor, consenters, signedSenders, signedReceivers

Field	Type	Description
instructor	Party	Party instructing settlement (and the creation of the <code>Instruction</code>).
consenters	Parties	Parties consenting with the creation of the <code>Instruction</code> .
settlers	Parties	Any of the parties can trigger the settlement.
batchId	Id	Trade identifier.
id	Id	Instruction identifier.
routedStep	RoutedStep	Routed settlement step.
settlementTime	Optional Time	Settlement time (if any).
allocation	Allocation	Allocation from the sender.
approval	Approval	Approval from the receiver.
signedSenders	Parties	Additional signatories, used to collect authorization.
signedReceivers	Parties	Additional signatories, used to collect authorization.
observers	PartiesMap	Observers.

Choice Archive

Controller: instructor, consenters, signedSenders, signedReceivers

Returns: ()

(no fields)

interface instance *I* for [Instruction](#)

interface instance *I* for [Instruction](#)

22.3.193.2 Data Types

type *T* = [Instruction](#)

Type synonym for `Instruction`.

22.3.194 Daml.Finance.Settlement.V4.RouteProvider.IntermediatedStatic

22.3.194.1 Templates

template [IntermediatedStatic](#)

Template which implements the `RouteProvider` interface. It is used to discover the settlement route for each settlement `Step`, i.e., `RoutedSteps`\s. For each instrument to settle as part of the batch, a hierarchy of intermediaries is specified in `paths`. This hierarchy is used to generate the `RoutedStep`\s.

Signatory: provider

Field	Type	Description
provider	Party	Party providing the facility.
observers	Parties	Observers.
paths	Map Text Hierarchy	Hierarchical paths used to settle holding transfers. A path is specified for each instrument label.

Choice Archive
 Controller: provider
 Returns: ()
 (no fields)
interface instance *I* for *IntermediatedStatic*

22.3.195 Daml.Finance.Settlement.V4.RouteProvider.SingleCustodian

22.3.195.1 Templates

template *SingleCustodian*

Template which implements the `RouteProvider` interface. It is used to transform each settlement `Step` into a `RoutedStep` using a single custodian.

Signatory: provider

Field	Type	Description
provider	<i>Party</i>	Party providing the facility.
observers	<i>Parties</i>	Observers.
custodian	<i>Party</i>	The custodian to be used to route each <code>Step</code> .

Choice Archive
 Controller: provider
 Returns: ()
 (no fields)
interface instance *I* for *SingleCustodian*

22.3.196 Daml.Finance.Util.V4.Common

22.3.196.1 Functions

notNull : `[a] -> Bool`

Checks if the input list is not empty.

sortAndGroupOn : `Ord k => (a -> k) -> [a] -> [[a]]`

Like `List.groupOn`, but sorts the list first.

22.3.197 Daml.Finance.Util.V4.Date.Calendar

22.3.197.1 Functions

merge : `[HolidayCalendarData] -> HolidayCalendarData`

Merge multiple holiday calendars into a single one. `id`'s are concatenated by `,`.

isHoliday : `HolidayCalendarData -> Date -> Bool`

Check if `Date` is a holiday.

isBusinessDay : `HolidayCalendarData -> Date -> Bool`

Check if `Date` is a business day.

nextBusinessDay : *HolidayCalendarData* -> *Date* -> *Date*

Get next business day.

previousBusinessDay : *HolidayCalendarData* -> *Date* -> *Date*

Get previous business day.

nextOrSameBusinessDay : *HolidayCalendarData* -> *Date* -> *Date*

Get next or same business day.

previousOrSameBusinessDay : *HolidayCalendarData* -> *Date* -> *Date*

Get previous or same business day.

nextSameOrLastInMonthBusinessDay : *HolidayCalendarData* -> *Date* -> *Date*

Get next or same business day if before end of month. Otherwise get last business day in month.

previousSameOrFirstInMonthBusinessDay : *HolidayCalendarData* -> *Date* -> *Date*

Get previous or same business day if before end of month. Otherwise get first business day in month.

addBusinessDays : *HolidayCalendarData* -> *Int* -> *Date* -> *Date*

Add business days to a Date.

adjustDate : *HolidayCalendarData* -> *BusinessDayConventionEnum* -> *Date* -> *Date*

Adjust date according to the given business day convention.

22.3.198 Daml.Finance.Util.V4.Date.DayCount

22.3.198.1 Functions

calcDcf : *DayCountConventionEnum* -> *Date* -> *Date* -> *Decimal*

Calculates the day count fraction given the corresponding convention. Currently 30E360 is not supported as we do not want to expose the maturity date of the product as an additional parameter.

calcPeriodDcf : *DayCountConventionEnum* -> *SchedulePeriod* -> *Bool* -> *Date* -> *ScheduleFrequency* -> *Decimal*

Calculate day count fraction for a schedule period. It takes the following parameters:

DayCountConventionEnum: to specify which day count convention should be used

SchedulePeriod: the schedule period for which the day count fraction should be calculated

Bool: Whether day count fraction should be calculated on adjusted dates (if False: unadjusted dates)

Date: The maturity date of the instrument

Frequency: the frequency of the schedule period

calcPeriodDcfActActIsda : *SchedulePeriod* -> *Bool* -> *Date* -> *Decimal*

Calculate Actual Actual day count fraction according to the ISDA method.

calcPeriodDcfActActIsma : *SchedulePeriod* -> *Bool* -> *Date* -> *ScheduleFrequency* -> *Decimal*

Calculate Actual Actual day count fraction according to the ISMA method.

calcDcfActActAfb : *Date* -> *Date* -> *Decimal*

calcDcfAct360 : *Date* -> *Date* -> *Decimal*

calcDcfAct365Fixed : *Date* -> *Date* -> *Decimal*

calcDcfAct365L : *Date* -> *Date* -> *Decimal*

calcDcf30360 : [Date](#) -> [Date](#) -> [Decimal](#)

calcDcf30360Icma : [Date](#) -> [Date](#) -> [Decimal](#)

calcDcf30E360 : [Bool](#) -> [Date](#) -> [Date](#) -> [Decimal](#)
Calculate 30E/360 day count fraction.

22.3.199 Daml.Finance.Util.V4.Date.RollConvention

22.3.199.1 Functions

next : [Date](#) -> [Period](#) -> [RollConventionEnum](#) -> [Date](#)

Get next periodic (daily [D](#) and weekly [W](#) not supported) date according to a given roll convention.

previous : [Date](#) -> [Period](#) -> [RollConventionEnum](#) -> [Date](#)

Get previous periodic (daily [D](#) and weekly [W](#) not supported) date according to a given roll convention.

addPeriod : [Date](#) -> [Period](#) -> [Date](#)

Add period to given date.

22.3.200 Daml.Finance.Util.V4.Date.Schedule

22.3.200.1 Functions

createSchedule : [[HolidayCalendarData](#)] -> [PeriodicSchedule](#) -> [Schedule](#)

Generate schedule from a periodic schedule.

22.3.201 Daml.Finance.Util.V4.Disclosure

This module contains default implementations for the methods of the `Disclosure` interface. These are used across multiple templates in the library.

22.3.201.1 Functions

setObserversImpl : ([HasCreate](#) t, [HasField](#) "observers" t [PartiesMap](#), [HasFromInterface](#) t [I](#), [HasToInterface](#) t [I](#), [HasInterfaceTypeRep](#) i, [HasToInterface](#) i [I](#), [HasToInterface](#) t i) => t -> [Optional](#) ([PartiesMap](#) -> [ContractId](#) i -> [Update](#) ([ContractId](#) i)) -> [SetObservers](#) -> [Update](#) ([ContractId](#) i)

Default implementation for `setObservers`. The `refUpdate` argument is used to update the corresponding contract `Reference` and can be set to `None` if your template does not have an accompanying `Reference` contract.

addObserversImpl : ([HasCreate](#) t, [HasField](#) "observers" t [PartiesMap](#), [HasFromInterface](#) t [I](#), [HasToInterface](#) t [I](#), [HasInterfaceTypeRep](#) i, [HasToInterface](#) i [I](#), [HasToInterface](#) t i) => t -> [Optional](#) ([PartiesMap](#) -> [ContractId](#) i -> [Update](#) ([ContractId](#) i)) -> [AddObservers](#) -> [Update](#) ([ContractId](#) i)

Default implementation for `addObservers`. The `refUpdate` argument is used to update the corresponding contract `Reference` and can be set to `None` if your template does not have an accompanying `Reference` contract.

removeObserversImpl : (HasCreate t, HasField "observers" t PartiesMap, HasFromInterface t I, HasToInterface t I, HasInterfaceTypeRep i, HasToInterface i I, HasToInterface t i) => t -> Optional (PartiesMap -> ContractId i -> Update (ContractId I)) -> ContractId I -> RemoveObservers -> Update (Optional (ContractId I))

Default implementation for removeObservers. The refUpdate argument is used to update the corresponding contract Reference and can be set to None if your template does not have an accompanying Reference contract.

22.3.202 Daml.Finance.Util.V4.Lockable

22.3.202.1 Functions

acquireImpl : (HasCreate t, HasSignatory t, HasFromInterface t Lockable, HasToInterface t Lockable) => Optional Lock -> (Optional Lock -> t) -> Acquire -> Update (ContractId Lockable)

Default implementation of acquire from the Lockable interface.

releaseImpl : (HasCreate t, HasFromInterface t Lockable, HasToInterface t Lockable) => Optional Lock -> (Optional Lock -> t) -> Release -> Update (ContractId Lockable)

Default implementation of release from the Lockable interface.

isValidLock : Optional Lock -> Bool

Check validity of lock. The lockers field must be non-empty if set.

Chapter 23

Canton

23.1 Introduction to Canton

Canton is a Daml ledger interoperability protocol. Parties that are hosted on different participant nodes can transact using smart contracts written in Daml and the Canton protocol. The Canton protocol allows you to connect different Daml ledgers into a single virtual global ledger. Daml, as the smart contract language, defines who is entitled to see and who is authorized to change any given contract. The Canton synchronization protocol enforces these visibility and authorization rules and ensures that the data is shared reliably with very high levels of privacy, even in the presence of malicious actors. The Canton network can be extended without friction with new parties, ledgers, and applications building on other applications. Extensions require neither a central managing entity nor consensus within the global network.

Canton faithfully implements the authorization and privacy requirements set out by Daml for its transactions.

Canton is written in Scala and runs as a Java process against a database (currently H2 and Postgres). Canton is *easy to set up*, *easy to develop on* and is *easy to operate safe and securely*.

23.2 Overview and Assumptions

In this section, we provide an overview of the Canton architecture and illustrate the high-level flows, entities (defining trust domains) and components. We then state the trust assumptions we make on the different entities and the assumptions on communication links.

Canton is designed to fulfill its *high-level requirements*. Before reading this section, you should be familiar with the Daml language and the *hierarchical transactions* of the DA ledger model.

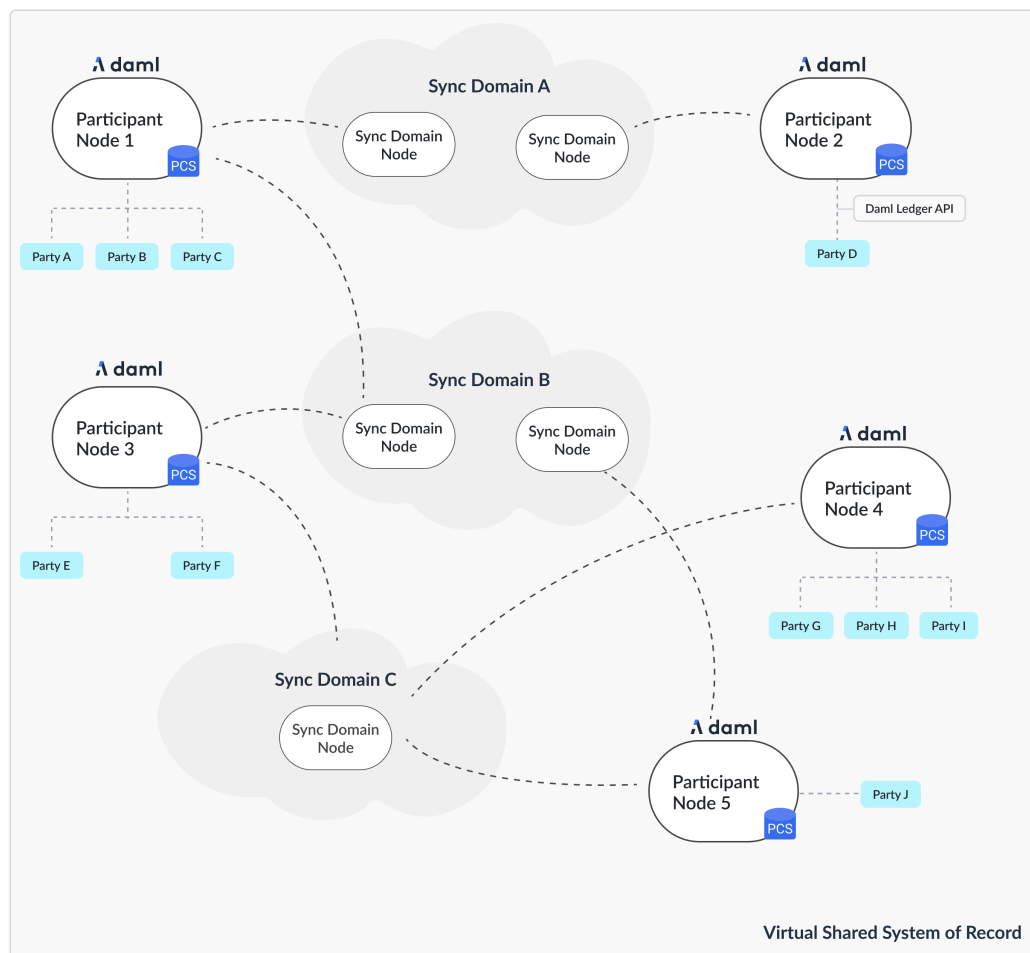

Fig. 1: Parties are hosted on participant nodes. Applications connect as parties to their participant node using the Ledger API. The participant node runs the Daml interpreter for the locally installed Daml smart contract code and stores the smart contracts in the *private contract store (PCS)*. The participants connect to sync domains and synchronize their states with other participants by exchanging Canton protocol messages with other participants leveraging the sync domain services. The use of the Canton protocol creates a virtual global ledger.

23.2.1 Canton 101

23.2.1.1 A Basic Example

We will use a simple delivery-versus-payment (DvP) example to provide some background on how Canton works. Alice and Bob want to exchange an IOU given to Alice by a bank for some shares that Bob owns. We have four parties: Alice (aka A), Bob (aka B), a Bank and a share registry SR. There are also three types of contracts:

1. an IOU contract, always with Bank as the backer
2. a Share contract, always with SR as the registry
3. a DvP contract between Alice and Bob

Assume that Alice has a `swap` choice on a DvP contract instance that exchanges an IOU she owns for a Share that Bob has. We assume that the IOU and Share contract instances have already been allocated in the DvP. Alice wishes to commit a transaction executing this swap choice; the transaction has the following structure:

23.2.1.2 Transaction Processing in Canton

In Canton, committing the example transaction consists of two steps:

1. Alice's participant prepares a **confirmation request** for the transaction. The request provides different views on the transaction; participants see only the subtransactions exercising, fetching or creating contracts on which their parties are stakeholders (more precisely, the subtransactions where these parties are *informees*). The views for the DvP, and their recipients, are shown in the figure below. Alice's participant submits the request to a **sequencer**, who orders all confirmation requests on a Canton sync domain; whenever two participants see the same two requests, they will see them according to this sequencer order. The sequencer has only two functions: ordering messages and delivering them to their stated recipients. The message contents are encrypted and not visible to the sequencer.
2. The recipients then check the validity of the views that they receive. The validity checks cover four aspects:
 1. validity as *defined* in the DA ledger model: *consistency*, (mainly: no double spends), *conformance* (the view is a result of a valid Daml interpretation) and *authorization* (guaranteeing

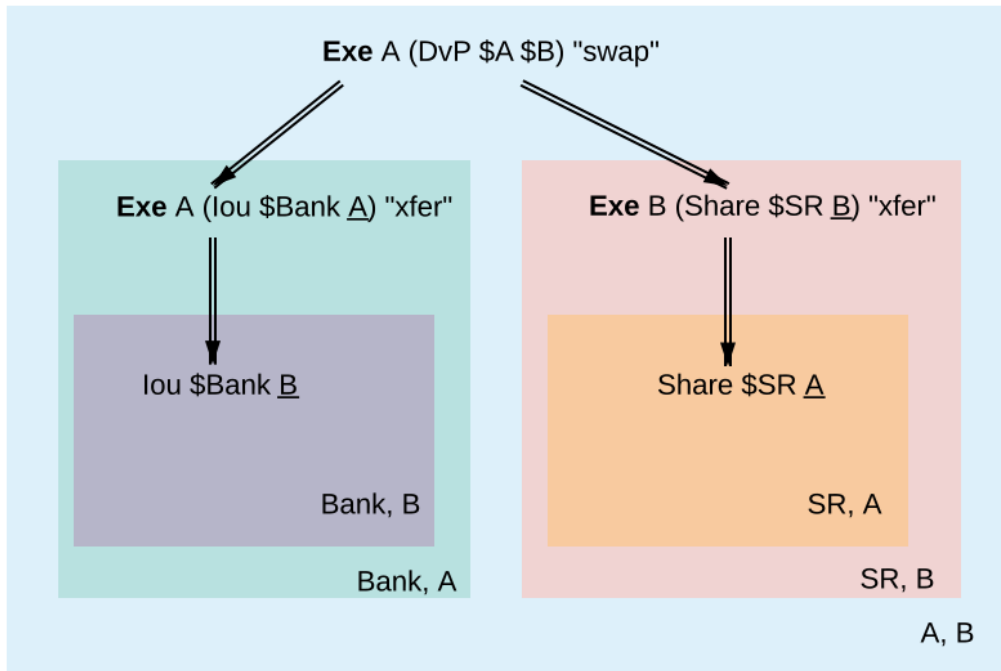

Fig. 2: Views in the transaction; each box represents a transaction part visible to the participants in its bottom-right corner. A participant might receive several views, some of which can be nested.

that the actors and submitters are allowed to perform the view's action)

2. authenticity (guaranteeing that the submitters are who they claim to be).
3. transparency (guaranteeing that participants who should be notified get notified).
4. consensus (guaranteeing that participants commit projections of the same transaction)

Conformance, authorization, authenticity, transparency, and consensus problems arise only due to submitter malice. Consistency problems can arise with no malice. For example, the IOU that is to be transferred to Bob might simply have already been spent. Based on the check's result, a subset of recipients called **confirming participants** then prepares a (positive or negative) **mediator response** for each view separately. A **confirmation policy** associated with the request specifies which participants must confirm, given the transaction's informees. The confirming participants send their responses to a **mediator**, another special entity that aggregates the responses into a single verdict for the entire confirmation request. The mediator serves to hide the participants' identities from each other (so that Bank and SR do not need to know that they are part of the same transaction). Like the sequencer, the mediator does not learn the transactions' contents. Instead, Alice's participant, in addition to sending the request, also simultaneously notifies the mediator about the informees of each view. The mediator receives a version of the transaction where only the informees of a view are visible and the contents blinded, as conceptually visualized in the diagram below. From this, the mediator derives which (positive) mediator responses are necessary in order to decide the confirmation request as **approved**.

Requests submitted by malicious participants can contain bogus views. As participants can see only parts of requests (due to privacy reasons), upon receiving an approval for a request, each participant locally filters out the bogus views that are visible to it, and **accepts** all remaining valid views of an approved confirmation request. Under the confirmation policy's trust assumptions, the protocol ensures that the local decisions of honest participants match for all views that they jointly see. The protocol thus provides a virtual shared ledger between the participants, whose transactions consist of such valid views. Once approved, the accepted views

Fig. 3: In the informee tree for the mediator, all transaction contents are blinded.

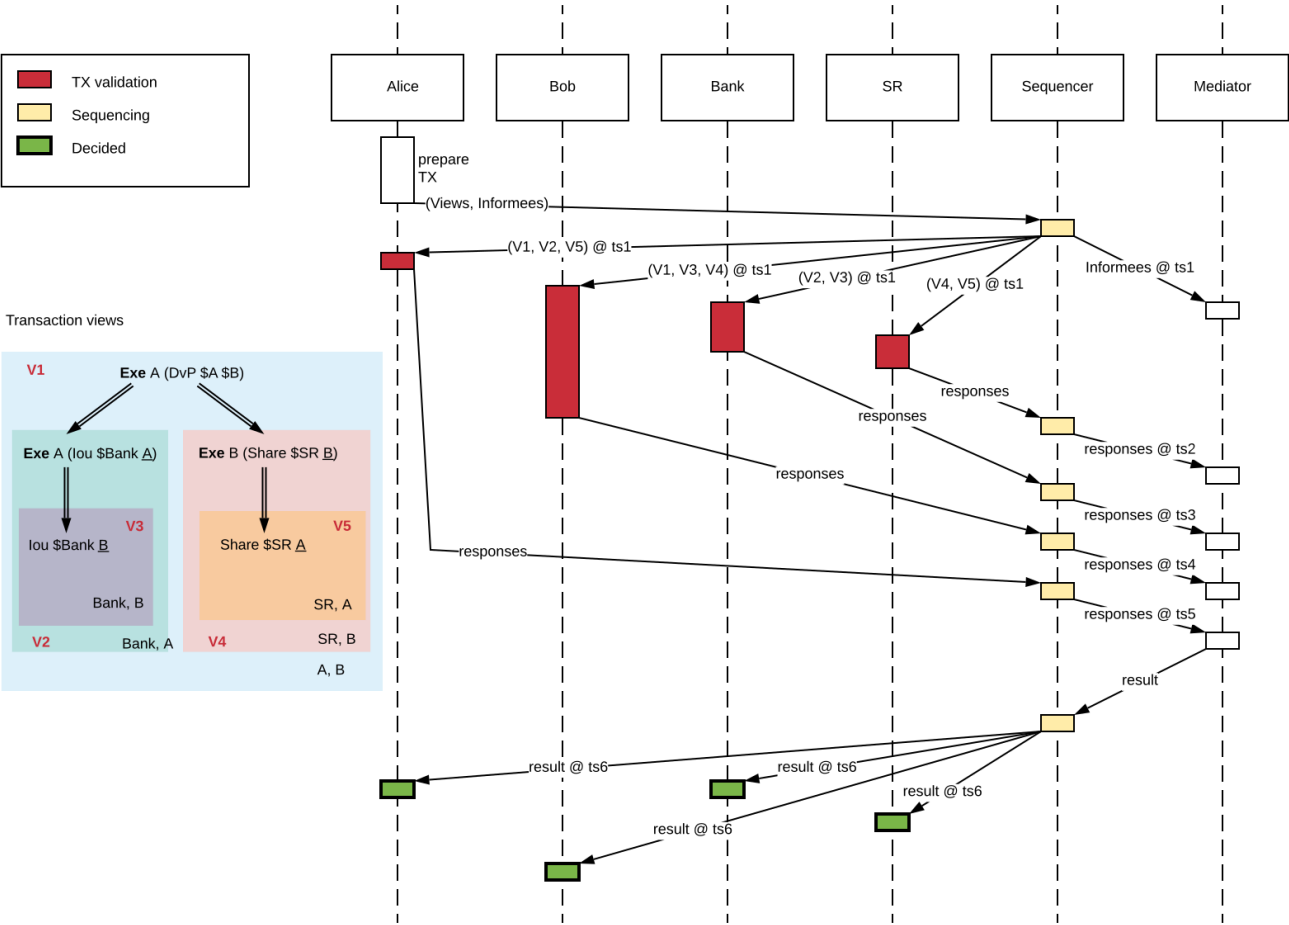

are **final**, i.e., they will never be removed from the participants' records or the virtual ledger.

We can represent the confirmation workflow described above by the following message sequence diagram, assuming that each party in the example runs their own participant node.

The sequencer and the mediator, together with a so-called **topology manager** (described shortly), constitute a **Canton Sync Domain**. All messages within the sync domain are exchanged over the sequencer, which ensures a **total order** between all messages exchanged within a sync domain.

The total ordering ensures that participants see all confirmation requests and responses in the same order. The Canton protocol additionally ensures that all non-Byzantine (i.e. not malicious or compromised) participants see their shared views (such as the exercise of the lou transfer, shared between the participants of Bank and A) in the same order, even with Byzantine submitters. This has the following implications:

1. The correct mediator response for each view is always uniquely determined, because Daml is deterministic. However, for performance reasons, we allow occasional incorrect negative responses, when participants start behaving in a Byzantine fashion or under contention. The system provides honest participants with evidence of either the correctness of their responses or the reason for the incorrect rejections.
2. The global ordering creates a (virtual) **global time** within a sync domain, measured at the sequencer; participants learn that time has progressed whenever they receive a message from the sequencer. This global time is used for detecting and resolving conflicts and determining when timeouts occur. Conceptually, we can therefore speak of a step happening at several participants simultaneously with respect to this global time, although each participant performs this step at a different physical time. For example, in the above *message sequence diagram*, Alice, Bob, the Bank, and the share registry's participants receive the confirmation request at different physical times, but conceptually this happens at the timestamp *ts1* of the global time, and similarly for the result message at timestamp *ts6*.

In this document, we focus on the basic version of Canton, with just a single sync domain. Canton also supports connecting a participant to multiple sync domains and transferring contracts between sync domains (see [composability](#)).

As mentioned in the introduction, the main challenges for Canton are reconciling integrity and privacy concerns while ensuring progress with the confirmation-based design, given that parties might be overloaded, offline, or simply refusing to respond. The main ways we cope with this problem are as follows:

We use timeouts: if a transaction's validity cannot be determined after a timeout (which is a sync domain-wide parameter), the transaction is rejected.

Flexible confirmation policies: To offer a trade-off between trust, integrity, and liveness, we allow Canton sync domains to choose their *confirmation policies*. Confirmation policies specify which participants need to confirm which views. This enables the mediator to determine the sufficient conditions to declare a request approved. Of particular interest is the *VIP confirmation policy*, applicable to transactions that involve a trusted (VIP) party as an informee on every action. An example of a VIP party is a market operator. The policy ensures ledger validity assuming the VIP party's participants behave correctly; incorrect behavior can still be detected and proven in this case, but the fallout must be handled outside of the system. Another important policy is the *signatory confirmation policy*, in which all signatories and actors are required to confirm. This requires a lower level of trust compared to the VIP confirmation policy sacrificing liveness when participants hosting signatories or actors are unresponsive. Another policy is the *full confirmation policy*, in which all informees are required to confirm. This requires the lowest level of trust, but sacrifices liveness when some of the involved participants are unresponsive.

23.2.1.3 Conflict Detection

Participants detect conflicts between concurrent transactions by locking the contracts that a transaction consumes. The participant locks a contract when it validates the confirmation request of a transaction that archives the contract. The lock indicates that the contract might be archived. When the mediator's decision arrives later, the contract is either archived or unlocked, depending on whether the transaction is committed or rolled back. Transactions that attempt to use a locked (i.e., potentially archived) contract are rejected. This design decision is based on the optimistic assumption that transactions are typically accepted; the later conflicting transaction can therefore be pessimistically rejected.

The next three diagrams illustrate locking and pessimistic rejections using the *counteroffer* example from the DA ledger model. There are two transactions and three parties and every party runs their own participant node.

The painter *P* accepts *A*'s *Counteroffer* in transaction tx1. This transaction consumes two contracts:

- The IOU between *A* and the *Bank*, referred to as *c1*.
- The *Counteroffer* with stakeholders *A* and *P*, referred to as *c2*.

The created contracts (the new IOU and the *PaintAgreement*) are irrelevant for this example.

Suppose that the *Counteroffer* contains an additional consuming choice controlled by *A*, e.g., *Alice* can retract her *Counteroffer*. In transaction tx2, *A* exercises this choice to consume the *Counteroffer* *c2*.

Since the messages from the sequencer synchronize all participants on the (virtual) global time, we may think of all participants performing the locking, unlocking, and archiving simultaneously.

In the first diagram, the sequencer sequences tx1 before tx2. Consequently, A and the Bank lock c1 when they receive the confirmation request, and so do A and P for c2. So when tx2 later arrives at A and P, the contract c2 is locked. Thus, A and P respond with a rejection and the mediator follows suit. In contrast, all stakeholders approve tx1; when the mediator's approval arrives at the participants, each participant archives the appropriate contracts: A archives c1 and c2, the Bank archives c1, and P archives c2.

Fig. 4: When two transactions conflict while they are in flight, the later transaction is always rejected.

The second diagram shows the scenario where A's retraction is sequenced before P's acceptance of the Counteroffer. So A and P lock c2 when they receive the confirmation request for tx2 from the sequencer and later approve it. For tx1, A and P notice that c2 is possibly archived and therefore reject tx1, whereas everything looks fine for the Bank. Consequently, the Bank and, for consistency, A lock c1 until the mediator sends the rejection for tx1.

Fig. 5: Transaction tx2 is now submitted before tx1. The consumed contract c1 remains locked by the rejected transaction until the mediator sends the result message.

Note: In reality, participants approve each view individually rather than the transaction as a whole. So A sends two responses for tx1: An approval for c1's archival and a rejection for c2's archival. The diagrams omit this technicality.

The third diagram shows how locking and pessimistic rejections can lead to unnecessary rejections. Now, the painter's acceptance of tx1 is sequenced before Alice's retraction like in the [first diagram](#), but the lou between A and the Bank has already been archived earlier. The painter receives only the view for c2, since P is not a stakeholder of the lou c1. Since everything looks fine, P locks c2 when the confirmation request for tx1 arrives. For consistency, A does the same, although A already knows that the transaction will fail because c1 is archived. Hence, both P and A reject tx2 because it tries to consume the locked contract c2. Later, when tx1's rejection arrives, c2 becomes active again, but the transaction tx2 remains rejected.

Fig. 6: Even if the earlier transaction tx1 is rejected later, the later conflicting transaction tx2 remains rejected and the contract remains locked until the result message.

23.2.1.4 Time in Canton

The connection between time in Daml transactions and the time defined in Canton is explained in the respective [ledger model section on time](#).

The respective section introduces *ledger time* and *record time*. The *ledger time* is the time the participant (or the application) chooses when computing the transaction prior to submission. We need the participant to choose this time as the transaction is pre-computed by the submitting participant and this transaction depends on the chosen time. The *record time* is assigned by the sequencer when registering the confirmation request (initial submission of the transaction).

There is only a bounded relationship between these times, ensuring that the *ledger time* must be in a pre-defined bound around the *record time*. The tolerance is defined on the sync domain as a sync domain parameter, known to all participants:

```
canton.domains.mydomain.parameters.ledger-time-record-time-tolerance
```

The bounds are symmetric in Canton, so the Canton sync domain parameter `ledger-time-record-time-tolerance` equals the `skew_min` and `skew_max` parameters from the ledger model.

Note: Canton does not support querying the time model parameters via the ledger API, as the time model is a per-sync domain property and this cannot be properly exposed on the respective ledger API endpoint.

Checking that the *record time* is within the required bounds is done by the validating participants and is visible to everyone. The sequencer does not know the *ledger time* and therefore cannot perform this validation.

Therefore, a submitting participant cannot control the output of a transaction depending on *record time*, as the submitting participant does not know exactly the point in time when the transaction will be timestamped by the sequencer. But the participant can guarantee that a transaction will either be registered before a certain record time, or the transaction will fail.

23.2.1.5 Subtransaction Privacy

Canton splits a Daml transaction into views, as described above under [transaction processing](#). The submitting participant sends these views via the sync domain's sequencer to all involved participants on a need-to-know basis. This section explains how the views are encrypted, distributed, and stored so that only the intended recipients learn the contents of the transaction.

In the [above DvP example](#), Canton creates a view for each node, as indicated by the boxes with the different colors. Canton captures this hierarchical view structure in a Merkle-like tree. For example, the view for exercising the `xfer` choice conceptually looks as follows, where the hashes `0x...` commit to the contents of the hidden nodes and subtrees without revealing the content. In particular, the second leg's structure, contents, and recipients are completely hidden in the hash `0x1210...`.

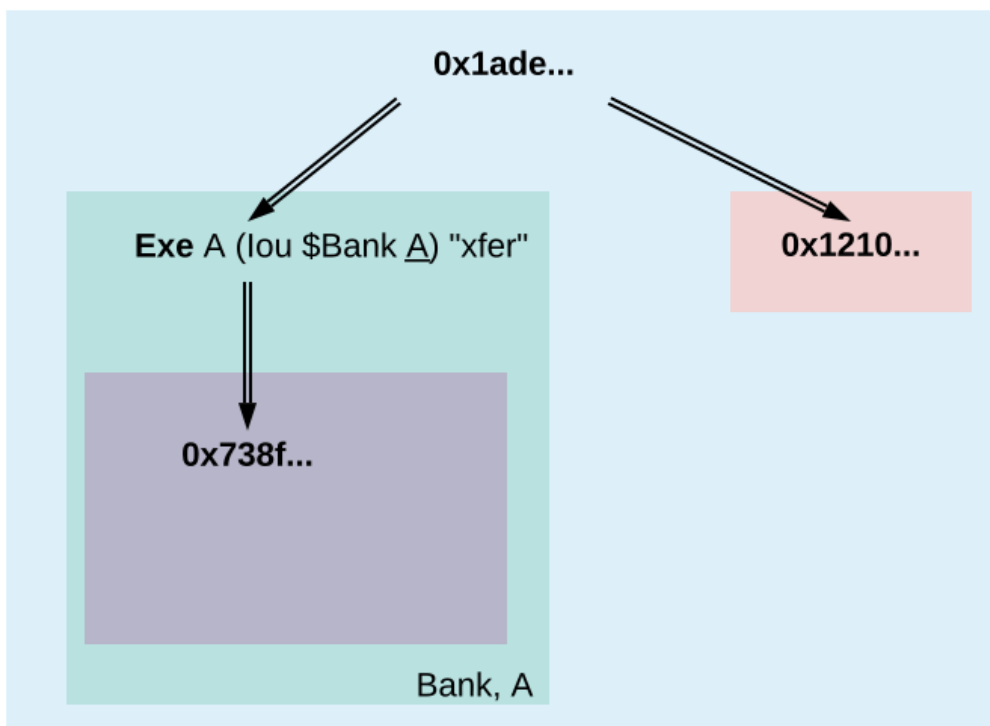

Fig. 7: Idealized Merkle tree for the view that exercises the `xfer` choice on Alice's lou.

The subview that creates the transferred lou has a similar structure, except that the hash `0x738f...` is now unblinded into the view content and the parent view's **Exercise** action is represented by its hash `0x8912...`.

Using the hashes, every recipient can correctly reconstruct their projection of the transaction from the views they receive.

As illustrated in the [confirmation workflow](#), the submitting participant sends the views to the participants hosting an informee or witness of a view's actions. This ensures **subtransaction privacy** as a participant receives only the data for the witnesses it hosts, not all of the transaction. Each Canton participant persists all messages it receives from the sequencer, including the views.

Moreover, Canton hides the transaction contents from the sync domain too. To that end, the submitting participant encrypts the views using the following encryption scheme:

1. It generates cryptographic randomness for the transaction, the transaction seed. From the transaction seed, a view seed is derived for each view following the hierarchical view structure,

Fig. 8: Idealized Merkle tree for the view that creates Bob's new Iou.

using a pseudo-random function. In the DvP example, a view seed $seed_0$ for the action at the top is derived from the transaction seed. The seed $seed_1$ for the view that exercises the transfer choice is derived from the parent view's seed $seed_0$, and similarly the seed $seed_2$ for the view that creates Bob's IOU is derived from $seed_1$.

2. For each view, it derives a symmetric encryption key from the view seed using a key derivation function. For example, the symmetric key for the view that creates Bob's IOU is derived from $seed_2$. Since the transaction seed is fresh for every submission and all derivations are cryptographically secure, each such symmetric key is used only once.
3. It encrypts the serialization of each view's Merkle tree with the symmetric key derived for this view. The view seed itself is encrypted with a short-lived symmetric session key that is generated for each distinct recipient informee group (set of participants that will receive the view). Finally this session key is encrypted with the public key of each participant hosting an informee of the view. If caching is enabled, the session key and the corresponding ciphertexts, which originated from asymmetrically encrypting this key with a participant's public key, are briefly stored in memory. This temporarily eliminates the need to asymmetrically encrypt/decrypt the session key for future similar views. The encrypted Merkle tree and the encrypted session key for each informee participant form the data that is sent via the sequencer.

Note: The view seed is encrypted only with the session key and this key is encrypted with the public key of the participants that host an informee, while the encrypted Merkle tree itself is also sent to participants hosting only witnesses. The latter participants can nevertheless decrypt the Merkle tree because they receive the view seed of a parent view and can derive the symmetric key of the witnessed view using the derivation functions.

Even though the sequencer persists the encrypted views for a limited period, the sync domain cannot access the symmetric session key, and, consequently, cannot decrypt the views unless it knows

the private key of one of the informee participants. Therefore, the transaction contents remain confidential with respect to the sync domain.

23.2.2 Synchronization Domain Entities

A Canton sync domain consists of three entities:

- the sequencer
- the mediator
- and the **topology manager**, providing a PKI infrastructure, and party to participant mappings.

We call these the **sync domain entities**. The high-level communication channels between the sync domain entities are depicted below.

In general, every sync domain entity can run in a separate trust domain (i.e., can be operated by an independent organization). In practice, we assume that all sync domain entities are run by a single organization and that the sync domain entities belong to a single trust domain.

Furthermore, each participant node runs in its own trust domain. Additionally, the participant may outsource a part of its identity management infrastructure, for example to a certificate authority. We assume that the participant trusts this infrastructure, that is, that the participant and its identity management belong to the same trust domain. Some participant nodes can be designated as **VIP nodes**, meaning that they are operated by trusted organizations. Such nodes are important for the VIP confirmation policy.

The generic term **member** will refer to either a sync domain or a participant node.

23.2.2.1 Sequencer

We now list the high-level requirements for the sequencer.

Ordering: The sequencer provides a [global total-order multicast](#) where envelopes are uniquely timestamped and the global ordering is derived from the timestamps. Instead of delivering a single envelope, the sequencer provides batching, that is, a list of individual envelopes is submitted. All of these envelopes get the timestamp of the batch they are contained in. Each envelope may have a different set of recipients; the envelopes in each recipient's batch are in the same order as in the sent batch.

Evidence: The sequencer provides the recipients with a cryptographic proof of authenticity for every batch it delivers, including evidence on the order of envelopes.

Sender and Recipient Privacy: The recipients do not learn the identity of the submitting participant. A recipient only learns the identities of recipients on a particular envelope from a batch if it is itself a recipient of that envelope.

Note: In the implementation, the recipients of an envelope are not a set of members (as indicated above), but a forest of sets of members. A member receives an envelope if it appears somewhere in the recipient forest. A member sees the nodes of the forest that contain itself as a recipient (as well as all descendants of such nodes), but it does not see the ancestors of such nodes. This feature is used to support bcc-style addressing of envelopes.

23.2.2.2 Mediator

The mediator's purpose is to compute the final result for a confirmation request and distribute it to the participants, ensuring that transactions are atomically committed across participants, while preserving the participants' privacy, by not revealing their identities to each other. At a high level, the mediator:

- collects mediator responses from participants,
- validates them according to the Canton protocol,
- computes the mediator verdict (approve/reject/timed out) according to the confirmation policy, and
- sends the result message.

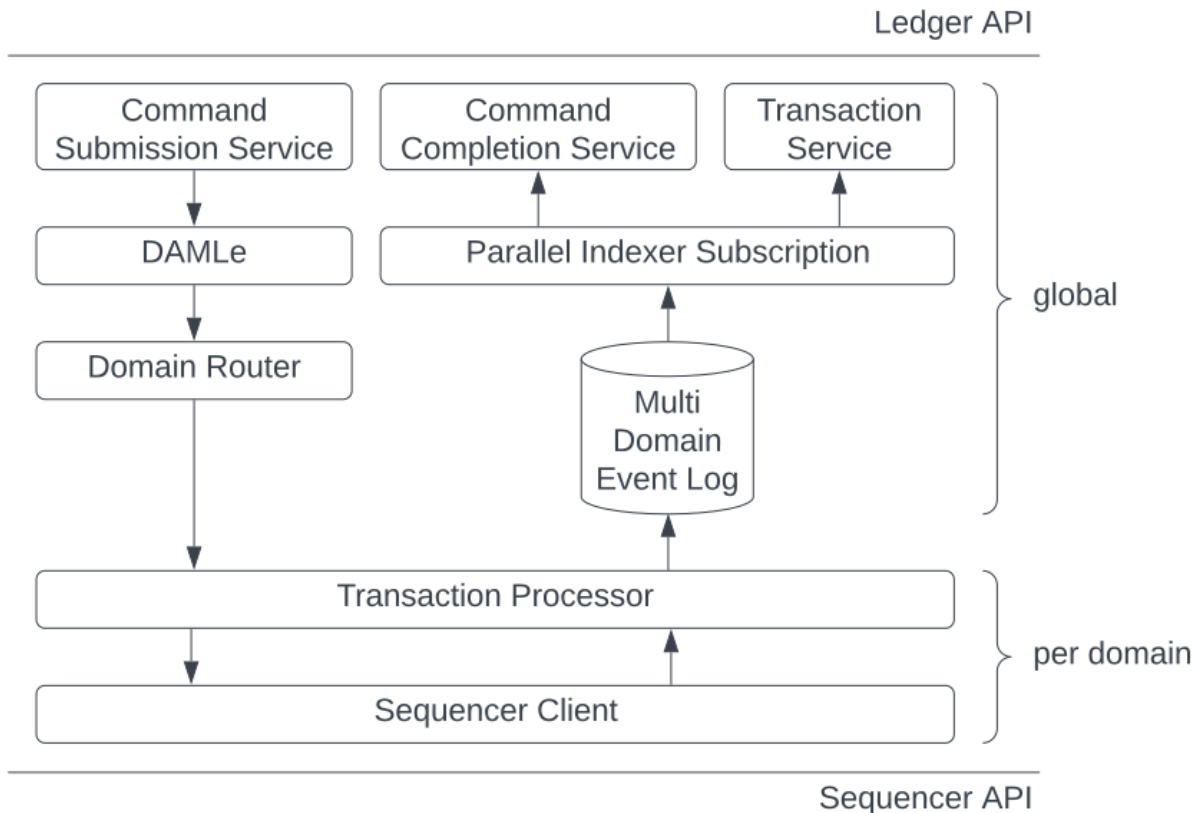

For auditability, the mediator also persists every finalized request together with its verdict in long-term storage and allows an auditor to retrieve messages from this storage.

23.2.2.3 Topology Manager

The topology manager allows participants to join and leave the Canton sync domain, and to register, revoke, and rotate public keys. It knows the parties **hosted** by a given participant. It defines the **trust level** of each participant. The trust level is either **ordinary** or **VIP**. A VIP trust level indicates that the participant is trusted to act honestly. A canonical example is a participant run by a trusted market operator.

23.2.3 Participant-Internal Canton Components

The following diagram shows the main components of a participant.

A ledger application uses the **ledger API** (at the top of the diagram) to send **commands** to a participant and to receive the corresponding events. The **command submission service** receives a command, parses it, and performs some basic validation. Next, the command is submitted to **DAMLe (DAML engine)**, which translates it to a **transaction**; a **command** consists only of a **root node** whereas a **transaction** also recursively contains all **consequences** of all exercise actions. Then, the **sync domain router** chooses a sync domain that is suitable for executing the transaction.

The **transaction processor** translates the transaction to a **confirmation request**; in particular, it computes the view decomposition, embeds the transaction into a Merkle tree, and creates different envelopes tailored to the different members validating the request. It uses the **sequencer client** to send the confirmation request to the mediator and all participants involved in the transaction.

The **transaction processor** also uses the sequencer client to **receive confirmation requests** from the sync domain, to **send mediator responses**, and to **receive the result messages** from the mediator.

The **multi-sync-domain event log** stores every committed request and every rollback. It also stores the order of events coming from the sync domains the participant is connected to. The **parallel indexer subscription** reads events from the multi-sync-domain event log and stores them in a format that is optimized for **fast read access**. The **command completion service** allows ledger applications to read the completions corresponding to the commands it has previously submitted. The **transaction service** provides a stream of all transactions that have been committed to the virtual shared ledger and are visible to the participant.

23.2.4 Trust Assumptions

The different sets of rules that Canton sync domains specify affect the security and liveness properties in different ways. In this section, we summarize the system model that we assume, as well as the trust assumptions. As specified in the [high-level requirements](#), the system provides guarantees only to honestly represented parties. Hence, every party must fully trust its participant (but no other participants) to execute the protocol correctly. In particular, signatures by participant nodes may be deemed as evidence of the party's action in the transaction protocol.

23.2.4.1 General Trust Assumptions

These assumptions are relevant for all system properties, except for privacy.

The sequencer is trusted to correctly provide a global total-order multicast service, with evidence and ensuring the sender and recipient privacy.

The mediator is trusted to produce and distribute all results correctly.

The sync domain topology manager (including the underlying public key infrastructure, if any) is operating correctly.

When a transaction is submitted with the VIP confirmation policy (in which case every action in the transaction must have at least one VIP informee), there exists an additional integrity assumption:

All VIP stakeholders must be hosted by honest participants, i.e., participants that run the transaction protocol correctly.

We note that the assumptions can be weakened by replicating the trusted entities among multiple organizations with a Byzantine fault tolerant replication protocol, if the assumptions are deemed too strong. Furthermore, we believe that with some extensions to the protocol we can make the violations of one of the above assumptions detectable by at least one participant in most cases, and often also provable to other participants or external entities. This would require direct communication between the participants, which we leave as future work.

23.2.4.2 Assumptions Relevant for Privacy

The following common assumptions are relevant for privacy:

The private keys of honest participants are not compromised, and all certificate authorities that the honest participants use are trusted.

The sequencer is privy to:

1. the submitters and recipients of all messages
2. the view structure of a transaction in a confirmation request, including informees and confirming parties
3. the confirmation responses (approve/reject/ill-formed) of confirmers.
4. encrypted transaction views
5. timestamps of all messages

The sequencer is trusted with not storing messages for longer than necessary for operational procedures (e.g., delivering messages to offline parties or for crash recovery).

The mediator is privy to:

1. the view structure of a transaction including informees and confirming parties, and the submitting party
2. the confirmation responses (approve/reject/ill-formed) of confirmers
3. timestamps of messages

The informees of a view are trusted with not violating the privacy of the other stakeholders in that same part. In particular, the submitter is trusted with choosing strong randomness for transaction and contract IDs. Note that this assumption is not relevant for integrity, as Canton ensures the uniqueness of these IDs.

When a transaction is submitted with the VIP confirmation policy, every action in the transaction must have at least one VIP informee. Thus, the VIP informees of the root actions are automatically privy to the entire contents of the transaction, according to the [ledger privacy model](#).

23.2.4.3 Assumptions Relevant for Liveness

In addition to the general trust assumptions, the following additional assumptions are relevant for liveness and bounded liveness functional requirements on the system: bounded decision time, and no unnecessary rejections:

All the sync domain entities in Canton (the sequencer, the mediator, and the topology manager) are highly available.

The sequencer is trusted to deliver the messages timely and fairly.

Participants hosting confirming parties according to the confirmation policy are assumed to be highly available and responding correctly. For example in the VIP confirmation policy, only the VIP participant needs to be available whereas in the signatory policy, liveness depends on the availability of all participants that host signatories and actors.

23.3 Canton Demo

The Canton demo is used to demonstrate the unique Canton capabilities:

Application Composability - Add new workflows at any time to a running system

Network Interoperability - Create workflows spanning across sync domains

Privacy - Canton uses data minimization and only shares data on a need-to-know basis.

Regulatory compliance - Canton can be used to even integrate personal sensitive information directly in workflows without fear of failing to be GDPR compliant.

The demo is a thin application running on top of a setup with 5 participant nodes and 2 sync domains. You can run it by downloading the [release package from github](#). Then, unpack and start it, using the following commands (or the zip equivalent)

```
tar zxvf canton-open-source-x.y.z.tar.gz
cd canton-open-source-x.y.z
bash start-demo.command
```

You need to replace `x.y.z` with the appropriate version number of the release you've downloaded. On Windows, you can just double-click the `start-demo-win.cmd` script in Windows explorer.

Note: The demo requires JavaFX. Please use a Java runtime of version 11 or greater.

If you don't want to run it yourself, you can also watch our recording.

The entire code base of the demo is included in the release package as `demo`.

23.4 Getting Started

Interested in Canton? This is the right place to start! You don't need any prerequisite knowledge, and you will learn:

- how to install Canton and get it up and running in a simple test configuration
- the main concepts of Canton
- the main configuration options
- some simple diagnostic commands on Canton
- the basics of Canton identity management
- how to upload and execute new smart contract code

23.4.1 Installation

Canton is a JVM application. To run it natively you need Java 11 or higher installed on your system. Alternatively Canton is available as a [docker image](#) (see [Canton docker instructions](#)).

Canton is platform-agnostic. For development purposes, it runs on macOS, Linux, and Windows. Linux is the supported platform for production.

Note: Windows garbles the Canton console output unless you are running Windows 10 and you enable terminal colors (e.g., by running `cmd.exe` and then executing `reg add HKCU\Console /v VirtualTerminalLevel /t REG_DWORD /d 1`).

To start, download the open source community edition [latest release](#) and extract the archive, or use the enterprise edition if you have access to it.

The extracted archive has the following structure:

```
.
├── bin
├── config
├── daml
├── dars
├── demo
├── drivers (enterprise)
├── examples
├── lib
└── ...
```

- `bin`: contains the scripts for running Canton (`canton` under Unix-like systems and `canton.bat` under Windows)
- `config`: contains a set of reference configuration files for each node type
- `daml`: contains the source code for some sample smart contracts
- `dars`: contains the compiled and packaged code of the above contracts
- `demo`: contains everything needed to run the interactive Canton demo
- `examples`: contains sample configuration and script files for the Canton console
- `lib`: contains the Java executables (JARs) needed to run Canton

This tutorial assumes you are running a Unix-like shell.

23.4.2 Starting Canton

While Canton supports a daemon mode for production purposes, in this tutorial we will use its console, a built-in interactive read-evaluate-print loop (REPL). The REPL gives you an out-of-the-box interface to all Canton features. In addition, as it's built using [Ammonite](#), you also have the full power of Scala if you need to extend it with new scripts. As such, any valid Scala expression can be typed inside the console:

```
@ Seq(1,2,3).map(_ * 2)
res1: Seq[Int] = List(2, 4, 6)
```

Navigate your shell to the directory where you extracted Canton. Then, run

```
bin/canton --help
```

to see the command line options that Canton supports. Alternatively to `bin/canton`, you can also start Canton directly with `java -jar lib/canton-*.jar`, assuming all other jar dependencies are in the `lib` folder, too.

Next, run

```
bin/canton -c examples/01-simple-topology/simple-topology.conf
```

This starts the console using the configuration file `examples/01-simple-topology/simple-topology.conf`. You will see the banner on your screen

```

  _____
 /         \
|           |
|  (  )  (  |
|  _ _  _ _ |
|  \_/_/_/_/|
 \         /
  _____

```

```
Welcome to Canton!
Type `help` to get started. `exit` to leave.
```

Type `help` to see the available commands in the console:

```
@ help
Top-level Commands
-----
exit - Leave the console
help - Help with console commands; type help("<command>") for detailed help for
      ↪<command>

Generic Node References
-----
domainManagers - All domain manager nodes (.all, .local, .remote)
..
```

You can also get help for specific Canton objects and commands:

```
@ help("participant1")
participant1
Manage participant 'participant1'; type 'participant1 help' or 'participant1 help(
↪ "<methodName>")' for more help
```

(continues on next page)

(continued from previous page)

```
@ participant1.help("start")
start
Start the instance
```

23.4.3 The Example Topology

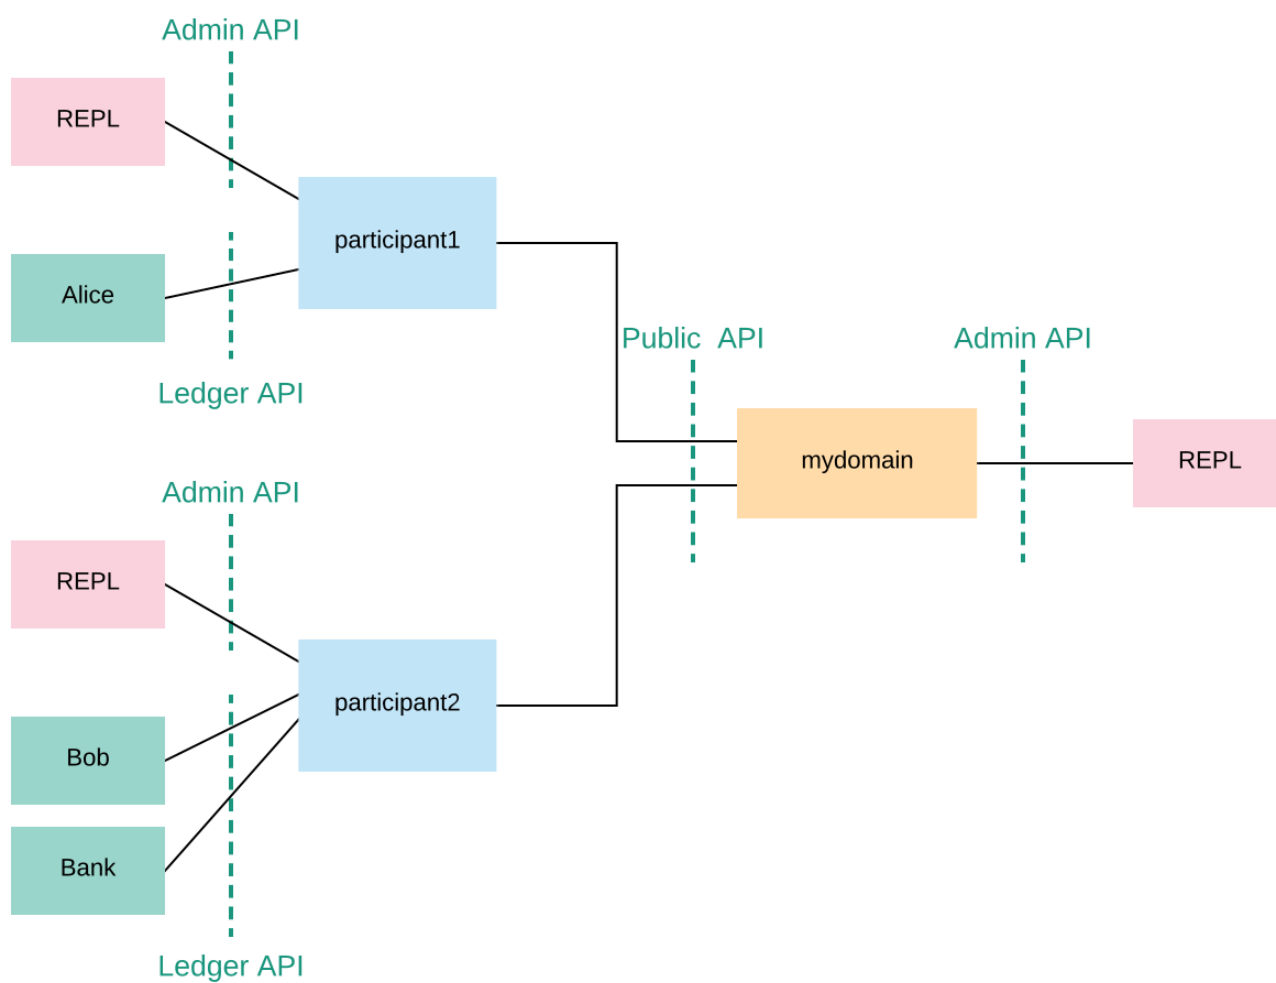

To understand the basic elements of Canton, let's briefly look at this starting configuration. It is written in the [HOCON](#) format as shown below. It specifies that you wish to run two *participant nodes*, whose local aliases are `participant1` and `participant2`, and a single *sync domain*, with the local alias `mydomain`. It also specifies the storage backend that each node should use (in this tutorial we're using in-memory storage), and the network ports for various services, which we will describe shortly.

```
canton {
  participants {
    participant1 {
      storage.type = memory
      admin-api.port = 5012
      ledger-api.port = 5011
    }
    participant2 {
      storage.type = memory
      admin-api.port = 5022
      ledger-api.port = 5021
      ledger-api.synchronize-vetting-on-upload = true
    }
  }
  domains {
    mydomain {
      init.domain-parameters.protocol-version = 7
      storage.type = memory
      public-api.port = 5018
      admin-api.port = 5019
    }
  }
  // enable ledger_api commands for our getting started guide
  features.enable-testing-commands = yes
}
```

To run the protocol, the participants must connect to one or more sync domains. To execute a *transaction* (a change that updates the shared contracts of several parties), all the parties' participant nodes must be connected to the same sync domain. In the remainder of this tutorial, you will construct a network topology that will enable the three parties Alice, Bob, and Bank to transact with each other, as shown here:

The participant nodes provide their parties with a [Ledger API](#) as a means to access the ledger. The parties can interact with the Ledger API manually using the console, but in practice these parties use applications to handle the interactions and display the data in a user-friendly interface.

In addition to the Ledger API, each participant node also exposes an *Admin API*. The Admin API allows the administrator (that is, you) to:

- manage the participant node's connections to sync domains
- add or remove parties to be hosted at the participant node
- upload new Daml archives
- configure the operational data of the participant, such as cryptographic keys
- run diagnostic commands

The sync domain exposes a *Public API* that is used by participant nodes to communicate with the synchronization sync domain. This must be accessible from where the participant nodes are hosted.

Similar to the participant node, a sync domain also exposes an Admin API for administration services. You can use these to manage keys, set sync domain parameters and enable or disable participant nodes within a sync domain, for example. The console provides access to the Admin APIs of the configured participants and sync domains.

Note: Canton's Admin APIs must not be confused with the `admin` package of the Ledger API. The `admin` package of the Ledger API provides services for managing parties and packages on *any Daml participant*. Canton's Admin APIs allows you to administrate *Canton-based nodes*. Both the `participant node` and the `sync domain` expose an Admin API with partially overlapping functionality.

Furthermore, participant nodes and sync domains communicate with each other through the Public API. The participants do not communicate with each other directly, but are free to connect to as many sync domains as they desire.

As you can see, nothing in the configuration specifies that our `participant1` and `participant2` should connect to `mydomain`. Canton connections are not statically configured - they are added dynamically. So first, let's connect the participants to the sync domain.

23.4.4 Connecting The Participant Nodes and Synchronization Domains

Using the console we can run commands on each of the configured participant nodes and sync domains. As such, we can check their health using the `health.status` command:

```
@ health.status
res5: EnterpriseCantonStatus = Status for Domain 'mydomain':
Domain id:☐
↪mydomain::12208e9bb9d1a378e0a94a2efdd4296f5122ba30e0133034491736247faf7fab5706
Uptime: 2.072132s
Ports:
  admin: 30191
  public: 30190
Connected Participants: None
Sequencer: SequencerHealthStatus(active = true)
Components:
  sequencer : Ok()
  memory_storage : Ok()
  domain-topology-sender : Ok()

Status for Participant 'participant1':
Participant id:☐
↪PAR::participant1::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce
Uptime: 1.45229s
Ports:
  ledger: 30186
```

(continues on next page)

(continued from previous page)

```

    admin: 30187
Connected domains: None
Unhealthy domains: None
Active: true
Components:
  memory_storage : Ok()
  crypto : Ok()
  sync-domain : Not Initialized
  sync-domain-ephemeral : Not Initialized
  sequencer-client : Not Initialized
  acs-commitment-processor : Not Initialized

Status for Participant 'participant2':
Participant id: ☐
↪PAR::participant2::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b
Uptime: 1.466668s
Ports:
  ledger: 30188
  admin: 30189
Connected domains: None
Unhealthy domains: None
Active: true
Components:
  memory_storage : Ok()
  crypto : Ok()
  sync-domain : Not Initialized
  sync-domain-ephemeral : Not Initialized
  sequencer-client : Not Initialized
  acs-commitment-processor : Not Initialized

```

We can also do this individually. As an example, to query the status of participant1:

```

@ participant1.health.status
res6: com.digitalasset.canton.health.admin.data.NodeStatus[com.digitalasset.
↪canton.health.admin.data.ParticipantStatus] = Participant id: ☐
↪PAR::participant1::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce
Uptime: 1.532608s
Ports:
  ledger: 30186
  admin: 30187
Connected domains: None
Unhealthy domains: None
Active: true
Components:
  memory_storage : Ok()
  crypto : Ok()
  sync-domain : Not Initialized
  sync-domain-ephemeral : Not Initialized
  sequencer-client : Not Initialized
  acs-commitment-processor : Not Initialized

```

or for the sync domain:

```

@ mydomain.health.status
res7: com.digitalasset.canton.health.admin.data.NodeStatus[mydomain.Status] = ☐
↪Domain id: ☐
↪mydomain::12208e9bb9d1a378e0a94a2efdd4296f5122ba30e0133034491736217f1d171d5970e8

```

(continues on next page)

(continued from previous page)

```

Uptime: 2.255564s
Ports:
  admin: 30191
  public: 30190
Connected Participants: None
Sequencer: SequencerHealthStatus(active = true)
Components:
  sequencer : Ok()
  memory_storage : Ok()
  domain-topology-sender : Ok()

```

Recall that the aliases `mydomain`, `participant1` and `participant2` come from the configuration file. By default, Canton will start and initialize the nodes automatically. This behavior can be overridden using the `--manual-start` command line flag or appropriate configuration settings.

For the moment, ignore the long hexadecimal strings that follow the node aliases; these have to do with Canton's identities, which we will explain shortly. As you see, the sync domain doesn't have any connected participants, and the participants are also not connected to any sync domains.

To connect the participants to the sync domain:

```
@ participant1.domains.connect_local(mydomain)
```

```
@ participant2.domains.connect_local(mydomain)
```

Now, check the status again:

```

@ health.status
res10: EnterpriseCantonStatus = Status for Domain 'mydomain':
Domain id: □
↪mydomain::12208e9bb9d1a378e0a94a2efdd4296f5122ba30e0133034491736247faf7fab5706
Uptime: 4.690512s
Ports:
  admin: 30191
  public: 30190
Connected Participants:
  PAR::participant2::12201c21f9b5...
  PAR::participant1::12202fe30927...
Sequencer: SequencerHealthStatus(active = true)
Components:
  sequencer : Ok()
  memory_storage : Ok()
  domain-topology-sender : Ok()
..

```

As you can read from the status, both participants are now connected to the sync domain. You can test the connection with the following diagnostic command, inspired by the ICMP ping:

```

@ participant1.health.ping(participant2)
res11: Duration = 218 milliseconds

```

If everything is set up correctly, this will report the `roundtrip time` between the Ledger APIs of the two participants. On the first attempt, this time will probably be several seconds, as the JVM is warming up. This will decrease significantly on the next attempt, and decrease again after JVM's

just-in-time compilation kicks in (by default this is after 10000 iterations).

You have just executed your first smart contract transaction over Canton. Every participant node has an associated built-in party that can take part in smart contract interactions. The `ping` command uses a particular smart contract that is by default pre-installed on every Canton participant. In fact, the command uses the Admin API to access a pre-installed application, which then issues Ledger API commands operating on this smart contract.

In theory, you could use your participant node's built-in party for all your application's smart contract interactions, but it's often useful to have more parties than participants. For example, you might want to run a single participant node within a company, with each employee being a separate party. For this, you need to be able to provision parties.

23.4.5 Canton Identities and Provisioning Parties

In Canton, the identity of each party, participant, or sync domain is represented by a *unique identifier*. A unique identifier consists of two components: a human-readable string and the fingerprint of a public key. When displayed in Canton the components are separated by a double colon. You can see the identifiers of the participants and the sync domains by running the following in the console:

```
@ mydomain.id
res12: DomainId = mydomain::12208e9bb9d1...
```

```
@ participant1.id
res13: ParticipantId = PAR::participant1::12202fe30927...
```

```
@ participant2.id
res14: ParticipantId = PAR::participant2::12201c21f9b5...
```

The human-readable strings in these unique identifiers are derived from the local aliases by default, but can be set to any string of your choice. The public key, which is called a *namespace*, is the root of trust for this identifier. This means that in Canton, any action taken in the name of this identity must be either:

- signed by this namespace key, or
- signed by a key that is authorized by the namespace key to speak in the name of this identity, either directly or indirectly (e.g., if `k1` can speak in the name of `k2` and `k2` can speak in the name of `k3`, then `k1` can also speak in the name of `k3`).

In Canton, it's possible to have several unique identifiers that share the same namespace - you'll see examples of that shortly. However, if you look at the identities resulting from your last console commands, you will see that they belong to different namespaces. By default, each Canton node generates a fresh asymmetric key pair (the secret and public keys) for its own namespace when first started. The key is then stored in the storage, and reused later in case the storage is persistent (recall that `simple-topology.conf` uses memory storage, which is not persistent).

23.4.6 Creating Parties

You will next create two parties, Alice and Bob. Alice will be hosted at `participant1`, and her identity will use the namespace of `participant1`. Similarly, Bob will use `participant2`. Canton provides a handy macro for this:

```
@ val alice = participant1.parties.enable("Alice")
alice : PartyId = Alice::12202fe30927...
```

```
@ val bob = participant2.parties.enable("Bob")
bob : PartyId = Bob::12201c21f9b5...
```

This creates the new parties in the participants' respective namespaces. It also notifies the sync domain of the new parties and allows the participants to submit commands on behalf of those parties. The sync domain allows this since, e.g., Alice's unique identifier uses the same namespace as `participant1` and `participant1` holds the secret key of this namespace. You can check that the parties are now known to `mydomain` by running the following:

```
@ mydomain.parties.list("Alice")
res17: Seq[ListPartiesResult] = Vector(
  ListPartiesResult(
    party = Alice::12202fe30927...,
    participants = Vector(
      ParticipantDomains(
        participant = PAR::participant1::12202fe30927...,
        domains = Vector(
          DomainPermission(domain = mydomain::12208e9bb9d1..., permission = ☐
↳ Submission)
        )
      )
    )
  )
)
```

and the same for Bob:

```
@ mydomain.parties.list("Bob")
res18: Seq[ListPartiesResult] = Vector(
  ListPartiesResult(
    party = Bob::12201c21f9b5...,
    participants = Vector(
      ParticipantDomains(
        participant = PAR::participant2::12201c21f9b5...,
        domains = Vector(
          DomainPermission(domain = mydomain::12208e9bb9d1..., permission = ☐
↳ Submission)
        )
      )
    )
  )
)
```

23.4.7 Extracting Identifiers

Canton identifiers can be long strings. They are normally truncated for convenience. However, in some cases we do have to extract these identifiers so they can be shared through other channels. As an example, if you have two participants that run in completely different locations, without a shared console, then you can't ping as we did before:

```
@ participant1.health.ping(participant2)
..
```

Instead, extract the participant ID of one node:

```
@ val extractedId = participant2.id.toProtoPrimitive
extractedId : String =
  ↪ "PAR::participant2::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b
  ↪ "
```

This ID can then be shared with the other participant, who in turn can parse the ID back into an appropriate object:

```
@ val p2Id = ParticipantId.tryFromProtoPrimitive(extractedId)
p2Id : ParticipantId = PAR::participant2::12201c21f9b5...
```

Subsequently, this ID can be used to ping as well:

```
@ participant1.health.ping(p2Id)
res22: Duration = 212 milliseconds
```

This also works for party identifiers:

```
@ val aliceAsStr = alice.toProtoPrimitive
aliceAsStr : String =
  ↪ "Alice::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce"
```

```
@ val aliceParsed = PartyId.tryFromProtoPrimitive(aliceAsStr)
aliceParsed : PartyId = Alice::12202fe30927...
```

Generally, a Canton identity boils down to a `UniqueIdentifier` and the context in which this identifier is used. This allows you to directly access the identifier serialization:

```
@ val p2UidString = participant2.id.uid.toProtoPrimitive
p2UidString : String =
  ↪ "participant2::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b
  ↪ "
```

```
@ val p2FromUid = ParticipantId(UniqueIdentifier.
  ↪ tryFromProtoPrimitive(p2UidString))
p2FromUid : ParticipantId = PAR::participant2::12201c21f9b5...
```

23.4.8 Provisioning Smart Contract Code

To create a contract between Alice and Bob, you must first provision the contract's code to both of their hosting participants. Canton supports smart contracts written in Daml. A Daml contract's code is specified using a Daml *contract template*; an actual contract is then a *template instance*. Daml templates are packaged into *Daml archives*, or DARs for short. For this tutorial, use the pre-packaged `dars/CantonExamples.dar` file. To provision it to both `participant1` and `participant2`, you can use the `participants.all` bulk operator:

```
@ participants.all.dars.upload("dars/CantonExamples.dar")
res27: Map[com.digitalasset.canton.console.ParticipantReference, String] = Map(
  Participant 'participant1' ->
  ↪ "1220948b69780faf57430a05ecf00acdfa284404dlea3be0422cd1bab0f13b21ff69",
  Participant 'participant2' ->
  ↪ "1220948b69780faf57430a05ecf00acdfa284404dlea3be0422cd1bab0f13b21ff69"
)
```

The bulk operator allows you to run certain commands on a series of nodes. Canton supports the bulk operators on the generic nodes:

```
@ nodes.local
res28: Seq[com.digitalasset.canton.console.LocalInstanceReferenceCommon] = []
  ↪ ArraySeq(Participant 'participant1', Participant 'participant2', Domain
  ↪ 'mydomain')
```

or on the specific node type:

```
@ participants.all
res29: Seq[com.digitalasset.canton.console.ParticipantReference] = []
  ↪ List(Participant 'participant1', Participant 'participant2')
```

Allowed suffixes are `.local`, `.all` or `.remote`, where the `remote` refers to [remote nodes](#), which we won't use here.

To validate that the DAR has been uploaded, run:

```
@ participant1.dars.list()
res30: Seq[com.digitalasset.canton.participant.admin.v0.DarDescription] = Vector(
  DarDescription(
    hash = "1220948b69780faf57430a05ecf00acdfa284404dlea3be0422cd1bab0f13b21ff69",
    name = "CantonExamples"
  ),
  DarDescription(
    hash = "122029f5ef0de5058a7330b7577570ad1130ad64dcaffb17cfe54db5738bd92d5e65",
    name = "AdminWorkflowsWithVacuuming"
  )
)
```

and on the second participant, run:

```
@ participant2.dars.list()
res31: Seq[com.digitalasset.canton.participant.admin.v0.DarDescription] = Vector(
  DarDescription(
    hash = "1220948b69780faf57430a05ecf00acdfa284404dlea3be0422cd1bab0f13b21ff69",
    name = "CantonExamples"
  ),
)
```

(continues on next page)

(continued from previous page)

```
DarDescription(  
  hash = "122029f5ef0de5058a7330b7577570ad1130ad64dcaffb17cfe54db5738bd92d5e65",  
  name = "AdminWorkflowsWithVacuuming"  
)  
)
```

One important observation is that you cannot list the uploaded DARs on the sync domain `mydomain`. You will simply get an error if you run `mydomain.dars.list()`. This is because the sync domain does not know anything about Daml or smart contracts. All the contract code is only executed by the involved participants on a need-to-know basis and needs to be explicitly enabled by them.

Now you are ready to start running smart contracts using Canton.

23.4.9 Executing Smart Contracts

Let's start by looking at some smart contract code. In our example, we'll have three parties, Alice, Bob and the Bank. In the scenario, Alice and Bob will agree that Bob has to paint her house. In exchange, Bob will get a digital bank note (I-Owe-You, IOU) from Alice, issued by a bank.

First, we need to add the Bank as a party:

```
@ val bank = participant2.parties.enable("Bank", waitForDomain = DomainChoice.All)  
bank : PartyId = Bank::12201c21f9b5...
```

You might have noticed that we've added a `waitForDomain` argument here. This is necessary to force some synchronization between the nodes to ensure that the new party is known within the distributed system before it is used.

Note: Canton alleviates most synchronization issues when interacting with Daml contracts. Nevertheless, Canton is a concurrent, distributed system. All operations happen asynchronously. Creating the Bank party is an operation local to `participant2`, and `mydomain` becomes aware of the party with a delay (see [Topology Transactions](#) for more detail). Processing and network delays also exist for all other operations that affect multiple nodes, though everyone sees the operations on the sync domain in the same order. When you execute commands interactively, the delays are usually too small to notice. However, if you're programming Canton scripts or applications that talk to multiple nodes, you might need some form of manual synchronization. Most Canton console commands have some form of synchronization to simplify your life and sometimes, using `utils.retry_until_true(...)` is a handy solution.

The corresponding Daml contracts that we are going to use for this example are:

```
module Iou where  
  
import Daml.Script  
  
data Amount = Amount {value: Decimal; currency: Text} deriving (Eq, Ord, Show)  
  
amountAsText (amount : Amount) : Text = show amount.value <> amount.currency  
  
template Iou  
  with
```

(continues on next page)

(continued from previous page)

```

payer: Party
owner: Party
amount: Amount
viewers: [Party]
where

  ensure (amount.value >= 0.0)

  signatory payer
  observer owner
  observer viewers

  choice Call : ContractId GetCash
    controller owner
    do
      create GetCash with payer; owner; amount

  choice Transfer : ContractId Iou
    with
      newOwner: Party
    controller owner
    do
      create this with owner = newOwner; viewers = []

  choice Share : ContractId Iou
    with
      viewer : Party

    observer houseOwner

```

(continues on next page)

(continued from previous page)

```
choice AcceptByOwner : ContractId Iou
with
  iouId : ContractId Iou
  controller houseOwner
do
  iouId2 <- exercise iouId Transfer with newOwner = painter
  paint <- create $ PaintHouse with painter; houseOwner
  return iouId2
```

We won't dive into the details of Daml, as this is [explained elsewhere](#). But one key observation is that the contracts themselves are passive. The contract instances represent the ledger and only encode the rules according to which the ledger state can be changed. Any change requires you to trigger some Daml contract execution by sending the appropriate commands over the Ledger API.

The Canton console gives you interactive access to this API, together with some utilities that can be useful for experimentation. The Ledger API uses [gRPC](#).

In theory, we would need to compile the Daml code into a DAR and then upload it to the participant nodes. We actually did this already by uploading the `CantonExamples.dar`, which includes the contracts. Now we can create our first contract using the template `Iou.Iou`. The name of the template is not enough to uniquely identify it. We also need the package ID, which is just the `sha256` hash of the binary module containing the respective template.

Find that package by running:

```
@ val pkgIou = participant1.packages.find("Iou").head
pkgIou : com.digitalasset.canton.participant.admin.v0.PackageDescription =
  ↳ PackageDescription(
    packageId = "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
    sourceDescription = "CantonExamples"
  )
```

Using this package-id, we can create the IOU:

```
@ val createIouCmd = ledger_api_utils.create(pkgIou.packageId, "Iou", "Iou", Map(
  ↳ "payer" -> bank, "owner" -> alice, "amount" -> Map("value" -> 100.0, "currency" ->
  ↳ "EUR"), "viewers" -> List()))
createIouCmd : com.daml.ledger.api.v1.commands.Command = Command(
  command = Create(
    value = CreateCommand(
      templateId = Some(
        value = Identifier(
          packageId =
  ↳ "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
  ..
```

and then send that command to the Ledger API:

```
@ participant2.ledger_api.commands.submit(Seq(bank), Seq(createIouCmd))
res35: com.daml.ledger.api.v1.transaction.TransactionTree = TransactionTree(
  transactionId =
  ↳ "12208a1fb1d49dc014ad8bc0d06ace8c98212e3e33a03f9b6a24a31b0db078e570f7",
  commandId = "a2531d01-aac6-442b-a66d-9711c10d1301",
  workflowId = "",
  effectiveAt = Some(
```

(continues on next page)

(continued from previous page)

```

    value = Timestamp(
      seconds = 1719407131L,
      nanos = 760048000,
      unknownFields = UnknownFieldSet(fields = Map())
    )
  ),
  offset = "0000000000000000015",
  ..

```

Here, we've submitted this command as party *Bank* on participant2. Interestingly, we can test here the Daml authorization logic. As the signatory of the contract is *Bank*, we can't have Alice submitting the contract:

```

@ participant1.ledger_api.commands.submit(Seq(alice), Seq(createIouCmd))
ERROR com.digitalasset.canton.integration.EnterpriseEnvironmentDefinition$$anon$3
↳ Request failed for participant1.
  GrpcClientError: INVALID_ARGUMENT/DAML_AUTHORIZATION_ERROR(8,e4d72bf0):
↳ Interpretation error: Error: node NodeId(0)
↳ (858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4:Iou:Iou)
↳ requires authorizers
↳ Bank::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b, but
↳ only
↳ Alice::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce
↳ were given
  Request: SubmitAndWaitTransactionTree(
    actAs = Alice::12202fe30927...,
    ..

```

And Alice cannot impersonate the Bank by pretending to be it (on her participant):

```

@ participant1.ledger_api.commands.submit(Seq(bank), Seq(createIouCmd))
ERROR com.digitalasset.canton.integration.EnterpriseEnvironmentDefinition$$anon$3
↳ Request failed for participant1.
  GrpcRequestRefusedByServer: NOT_FOUND/NO_DOMAIN_ON_WHICH_ALL_SUBMITTERS_CAN_
↳ SUBMIT(11,f96707c7): This participant can not submit as the given submitter on
↳ any connected domain
  Request: SubmitAndWaitTransactionTree(
    actAs = Bank::12201c21f9b5...,
    ..

```

Alice can, however, observe the contract on her participant by searching her Active Contract Set (ACS) for it:

```

@ val aliceIou = participant1.ledger_api.acs.find_generic(alice, _.templateId.
↳ isModuleEntity("Iou", "Iou"))
aliceIou : com.digitalasset.canton.admin.api.client.commands.
↳ LedgerApiTypeWrappers.WrappedCreatedEvent = WrappedCreatedEvent(
  event = CreatedEvent(
    eventId = "
↳ #12208a1fb1d49dc014ad8bc0d06ace8c98212e3e33a03f9b6a24a31b0db078e570f7:0",
    contractId =
↳ "0092044370539d4701d8abe6cdb4394bf6d153a8af301b7636b11e6316540527a5ca02122076d6b9fba170de
↳ ",
    ..

```

We can check Alice's ACS, which will show us all the contracts Alice knows about:

```
@ participant1.ledger_api.acs.of_party(alice)
res37: Seq[com.digitalasset.canton.admin.api.client.commands.
↳LedgerApiTypeWrappers.WrappedCreatedEvent] = List(
  WrappedCreatedEvent(
    event = CreatedEvent(
      eventId = "
↳#12208a1fb1d49dc014ad8bc0d06ace8c98212e3e33a03f9b6a24a31b0db078e570f7:0",
      contractId =
↳"0092044370539d4701d8abe6cdb4394bf6d153a8af301b7636b11e6316540527a5ca02122076d6b9fba170de
↳",
      templateId = Some(
        value = Identifier(
          packageId =
↳"858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
        ..

```

As expected, Alice does see exactly the contract that the Bank previously created. The command returns a sequence of wrapped `CreatedEvent`'s. This Ledger API data type represents the event of a contract's creation. The output is a bit verbose, but the wrapper provides convenient functions to manipulate the `CreatedEvents` in the Canton console:

```
@ participant1.ledger_api.acs.of_party(alice).map(x => (x.templateId, x.
↳arguments))
res38: Seq[(TemplateId, Map[String, Any])] = List(
  (
    TemplateId(
      packageId =
↳"858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
      moduleName = "Iou",
      entityName = "Iou"
    ),
    HashMap(
      "payer" ->
↳"Bank::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b",
      "viewers" -> List(elements = Vector()),
      "owner" ->
↳"Alice::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce",
      "amount.currency" -> "EUR",
      "amount.value" -> "100.0000000000"
    )
  )
)

```

Going back to our story, Bob now wants to offer to paint Alice's house in exchange for money. Again, we need to grab the package ID, as the Paint contract is in a different module:

```
@ val pkgPaint = participant1.packages.find("Paint").head
pkgPaint : com.digitalasset.canton.participant.admin.v0.PackageDescription =
↳PackageDescription(
  packageId = "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
  sourceDescription = "CantonExamples"
)

```

Note that the modules are compositional. The `Iou` module is not aware of the `Paint` module, but the `Paint` module is using the `Iou` module within its workflow. This is how we can extend any workflow in Daml and build on top of it. In particular, the Bank does not need to know about the `Paint` module

at all, but can still participate in the transaction without any adverse effect. As a result, everybody can extend the system with their own functionality. Let's create and submit the offer now:

```
@ val createOfferCmd = ledger_api_utils.create(pkgPaint.packageId, "Paint",
  ↳ "OfferToPaintHouseByPainter", Map("bank" -> bank, "houseOwner" -> alice,
  ↳ "painter" -> bob, "amount" -> Map("value" -> 100.0, "currency" -> "EUR")))
createOfferCmd : com.daml.ledger.api.v1.commands.Command = Command(
  command = Create(
    value = CreateCommand(
      templateId = Some(
        value = Identifier(
          packageId =
  ↳ "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
  ..
```

```
@ participant2.ledger_api.commands.submit_flat(Seq(bob), Seq(createOfferCmd))
res41: com.daml.ledger.api.v1.transaction.Transaction = Transaction(
  transactionId =
  ↳ "1220e4f1e3aaee9fbfa494d37fc29996376fccefc045eb99d3bd6df5e418066aeae5",
  commandId = "fe19a845-6018-4c44-8002-0a594ca48047",
  workflowId = "",
  effectiveAt = Some(
    value = Timestamp(
  ..
```

Alice will observe this offer on her node:

```
@ val paintOffer = participant1.ledger_api.acs.find_generic(alice, _.templateId.
  ↳ isModuleEntity("Paint", "OfferToPaintHouseByPainter"))
paintOffer : com.digitalasset.canton.admin.api.client.commands.
  ↳ LedgerApiTypeWrappers.WrappedCreatedEvent = WrappedCreatedEvent(
  event = CreatedEvent(
    eventId = "
  ↳ #1220e4f1e3aaee9fbfa494d37fc29996376fccefc045eb99d3bd6df5e418066aeae5:0",
    contractId =
  ↳ "00733bf85cb604a9f4c621f2ea22b579062b3698033187ec22b77350ba332989b3ca02122005c1a8076c82bc
  ↳ ",
    templateId = Some(
      value = Identifier(
  ..
```

23.4.10 Privacy

Looking at the ACS of Alice, Bob and the Bank, we note that Bob sees only the paint offer:

```
@ participant2.ledger_api.acs.of_party(bob).map(x => (x.templateId, x.arguments))
res43: Seq[(TemplateId, Map[String, Any])] = List(
  (
    TemplateId(
      packageId =
  ↳ "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
      moduleName = "Paint",
      entityName = "OfferToPaintHouseByPainter"
    ),
    HashMap(
```

(continues on next page)

(continued from previous page)

```

    "painter" ->
    ↪ "Bob::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b",
      "houseOwner" ->
    ↪ "Alice::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce",
      "bank" ->
    ↪ "Bank::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b",
      "amount.currency" -> "EUR",
      "amount.value" -> "100.0000000000"
  )
)
)

```

while the Bank sees the IOU contract:

```

@ participant2.ledger_api.acs.of_party(bank).map(x => (x.templateId, x.arguments))
res44: Seq[(TemplateId, Map[String, Any])] = List(
  (
    TemplateId(
      packageId =
    ↪ "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
      moduleName = "Iou",
      entityName = "Iou"
    ),
    HashMap(
      "payer" ->
    ↪ "Bank::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b",
      "viewers" -> List(elements = Vector()),
      "owner" ->
    ↪ "Alice::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce",
      "amount.currency" -> "EUR",
      "amount.value" -> "100.0000000000"
    )
  )
)
)

```

But Alice sees both on her participant node:

```

@ participant1.ledger_api.acs.of_party(alice).map(x => (x.templateId, x.
    ↪ arguments))
res45: Seq[(TemplateId, Map[String, Any])] = List(
  (
    TemplateId(
      packageId =
    ↪ "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
      moduleName = "Iou",
      entityName = "Iou"
    ),
    HashMap(
      "payer" ->
    ↪ "Bank::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b",
      "viewers" -> List(elements = Vector()),
      "owner" ->
    ↪ "Alice::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce",
      "amount.currency" -> "EUR",
      "amount.value" -> "100.0000000000"
    )
  )
)

```

(continues on next page)

(continued from previous page)

```

    )
  ),
  (
    TemplateId(
      packageId =
        ↪ "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
      moduleName = "Paint",
      entityName = "OfferToPaintHouseByPainter"
    ),
    HashMap(
      "painter" ->
        ↪ "Bob::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b",
      "houseOwner" ->
        ↪ "Alice::12202fe309276dbb798c9287d4ce7be55f88cab7f0997f0d2970dacc4c55bb9e12ce",
      "bank" ->
        ↪ "Bank::12201c21f9b56094e26ed8691d681ffb6393372d35c9a4641dc7628bd76eca2e776b",
      "amount.currency" -> "EUR",
      "amount.value" -> "100.0000000000"
    )
  )
)

```

If there were a third participant node, it wouldn't have even noticed that anything was happening, let alone have received any contract data. Or if we had deployed the Bank on that third node, that node would not have been informed about the Paint offer. This privacy feature goes so far in Canton that not even everybody within a single atomic transaction is aware of each other. This is a property unique to the Canton synchronization protocol, which we call *sub-transaction privacy*. The protocol ensures that only eligible participants will receive any data. Furthermore, while the node running `mydomain` does receive this data, the data is encrypted and `mydomain` cannot read it.

We can run such a step with sub-transaction privacy by accepting the offer, which will lead to the transfer of the Bank IOU, without the Bank learning about the Paint agreement:

```
@ import com.digitalasset.canton.protocol.LfContractId
```

```

@ val acceptOffer = ledger_api_utils.exercise("AcceptByOwner", Map("iouId" -> ↪
        ↪ LfContractId.assertFromString(aliceIou.event.contractId)), paintOffer.event)
acceptOffer : com.daml.ledger.api.v1.commands.Command = Command(
  command = Exercise(
    value = ExerciseCommand(
      templateId = Some(
        value = Identifier(
          packageId =
            ↪ "858e7bb622e5be4df263b88af6fad9af584e272423e8dde5dab8a2f58a8feaa4",
        ..

```

```

@ participant1.ledger_api.commands.submit_flat(Seq(alice), Seq(acceptOffer))
res48: com.daml.ledger.api.v1.transaction.Transaction = Transaction(
  transactionId =
    ↪ "12208b2c1806b66939b793d13221e8a5c35bca9a961714dc67a39c1c3f4980ed7159",
  commandId = "7a924bc4-f756-4f2d-bac6-065befb2fcb6",
  workflowId = "",
  effectiveAt = Some(
    value = Timestamp(
      ..

```

Note that the conversion to `LfContractId` was required to pass in the IOU contract ID as the correct type.

23.4.11 Your Development Choices

While the `ledger_api` functions in the Console can be handy for educational purposes, the Daml SDK provides you with much more convenient tools to inspect and manipulate the ledger content:

- [Daml script](#) for scripting
- [Json API](#) for browser based UIs
- [Bindings in a variety of languages](#) to build your own applications or automation
- The browser based [Navigator \(Deprecated\)](#)
- The console version [Navigator \(Deprecated\)](#)
- [Daml triggers \(Deprecated\)](#) for reactive operations
- [Daml REPL \(Deprecated\)](#) for interactive manipulations

All these tools work against the Ledger API.

23.4.12 Automation Using Bootstrap Scripts

You can configure a bootstrap script to avoid having to manually complete routine tasks such as starting nodes or provisioning parties each time Canton is started. Bootstrap scripts are automatically run after Canton has started and can contain any valid Canton Console commands. A bootstrap script is passed via the `--bootstrap` CLI argument when starting Canton. By convention, we use a `.canton` file ending.

For example, the bootstrap script to connect the participant nodes to the local domain and ping participant1 from participant2 (see [Starting and Connecting The Nodes](#)) is:

```
// start all local instances defined in the configuration file
nodes.local.start()

// Connect participant1 to mydomain using the connect macro.
// The connect macro will inspect the domain configuration to find the correct
// URL and Port.
// The macro is convenient for local testing, but obviously doesn't work in a
// distributed setup.
participant1.domains.connect_local(mydomain)

val mydomainPort = Option(System.getProperty("canton-examples.mydomain-port")).
  getOrElse("5018")

// Connect participant2 to mydomain using just the target URL and a local name we
// use to refer to this particular
// connection. This is actually everything Canton requires and this second type
// of connect call can be used
// in order to connect to a remote Canton domain.
//
// The connect call is just a wrapper that invokes the `domains.register`,
// `domains.get_agreement` and `domains.accept_agreement` calls.
//
// The address can be either HTTP or HTTPS. From a security perspective, we do
// assume that we either trust TLS to
// initially introduce the domain. If we don't trust TLS for that, we can also
// optionally include a so called
```

(continues on next page)

(continued from previous page)

```
// EssentialState that establishes the trust of the participant to the domain.
// Whether a domain will let a participant connect or not is at the discretion of
↳ the domain and can be configured
// there. While Canton establishes the connection, we perform a handshake,
↳ exchanging keys, authorizing the connection
// and verifying version compatibility.
participant2.domains.connect("mydomain", s"http://localhost:$mydomainPort")

// The above connect operation is asynchronous. It is generally at the discretion
↳ of the domain
// to decide if a participant can join and when. Therefore, we need to
↳ asynchronously wait here
// until the participant observes its activation on the domain. As the domain is
↳ configured to be
// permissionless in this example, the approval will be granted immediately.
utils.retry_until_true {
    participant2.domains.active("mydomain")
}

participant2.health.ping(participant1)
```

Note how we again use `retry_until_true` to add a manual synchronization point, making sure that `participant2` is registered, before proceeding to ping `participant1`.

23.4.13 What Next?

You are now ready to start using Canton for serious tasks. If you want to develop a Daml application and run it on Canton, we recommend the following resources:

1. Install the [Daml SDK](#) to get access to the Daml IDE and other tools, such as the Navigator.
2. Run through the [Daml SDK getting-started example](#) to learn how to build your own Daml applications on Canton.
3. Follow the [Daml documentation](#) to learn how to program new contracts, or check out the [Daml Examples](#) to find existing ones for your needs.
4. Use the [Navigator \(Deprecated\)](#) for easy Web-based access and manipulation of your contracts.

If you want to understand more about Canton:

1. Read the [requirements](#) that Canton was built for to find out more about the properties of Canton.
2. Read the [architectural overview](#) for more understanding of Canton concepts and internals.

If you want to deploy your own Canton nodes, consult the [installation guide](#).

23.5 Daml SDK and Canton

This tutorial shows how to run an application on a distributed setup using Canton instead of running it on the [Daml sandbox](#). This comes with a few known problems and this section explains how to work around them.

In this tutorial, you will learn how to run the [Create Daml App](#) example on Canton. This guide will teach you:

1. The main concepts of Daml

2. How to compile your own Daml Archive (DAR)
3. How to run the Create Daml App example on Canton
4. How to write your own Daml code
5. How to integrate a conventional application with Canton

If you haven't yet done so, please run through the [Getting Started with Canton](#) and the original [Daml getting started guide](#) to familiarise yourself with the example application. Then come back here to get the same example running on Canton.

23.5.1 Starting Canton

Follow the [Daml SDK installation guide](#) to get the SDK locally installed.

This guide has been tested with the SDK version 2.5.1. Set the environment variable `DAML_SDK_VERSION` to `2.5.1` so that subsequent `daml` commands use this version.

```
export DAML_SDK_VERSION=2.5.1
```

Starting from the location where you unpacked the Canton distribution, fetch the `create-daml-app` example into a directory named `create-daml-app` (as the example configuration files of `examples/04-create-daml-app` expect the files to be there):

```
daml new create-daml-app --template create-daml-app
```

Next, compile the Daml code into a DAR file (this will create the file `.daml/dist/create-daml-app-0.1.0.dar`), and run the code generation step used by the UI:

```
cd create-daml-app
daml build
daml codegen js .daml/dist/create-daml-app-0.1.0.dar -o ui/daml.js
```

You will also need to install the dependencies for the UI:

```
cd ui
npm install
```

Next, the original tutorial would ask you to start the Sandbox and the HTTP JSON API with `daml start`. We will instead start Canton using the distributed setup in `examples/04-create-daml-app`, and will later start the [HTTP JSON API](#) in a separate step.

Return to the directory where you unpacked the Canton distribution and start Canton with:

```
cd ../../
bin/canton -c examples/04-create-daml-app/canton.conf --bootstrap examples/04-
↪create-daml-app/init.canton
```

Note: If you get an `Compilation Failed` error, you may have to make the Canton binary executable with `chmod +x bin/canton`

This will start two participant nodes, allocate the parties Alice, Bob and Public and create corresponding users `alice` and `bob`. Each participant node will expose its own ledger API:

1. Alice will be hosted by `participant1`, with its ledger API on port 12011

2. Bob will be hosted by participant2, with its ledger API on port 12021

Note that the `examples/04-create-daml-app/init.canton` script performs a few setup steps to permission the parties and upload the DAR.

Leave Canton running and switch to a new terminal window.

23.5.2 Running the Create Daml App Example

Once Canton is running, start the HTTP JSON API:

Connected to the ledger api on port 12011 (corresponding to Alice's participant)
And connected to the UI on the default expected port 7575

```
DAML_SDK_VERSION=2.5.1 daml json-api \
--ledger-host localhost \
--ledger-port 12011 \
--http-port 7575 \
--allow-insecure-tokens
```

Leave this running. The UI can then be started from a third terminal window with:

```
cd create-daml-app/ui
REACT_APP_LEDGER_ID=participant1 npm start
```

Note that we have to configure the ledger ID used by the UI to match the name of the participant that we're running against. This is done using the environment variable `REACT_APP_LEDGER_ID`.

We can now log in as `alice`.

23.5.2.1 Connecting to participant2

You can log in as Bob using `participant2` by following essentially the same process as for `participant1`, adjusting the ports to correspond to `participant2`.

First, start another instance of the HTTP JSON API, this time using the options `--ledger-port=12021` and `--http-port 7576`. 12021 corresponds to `participant2`'s ledger port, and 7576 is a new port for another instance of the HTTP JSON API:

```
DAML_SDK_VERSION=2.5.1 daml json-api \
--ledger-host localhost \
--ledger-port 12021 \
--http-port 7576 \
--allow-insecure-tokens
```

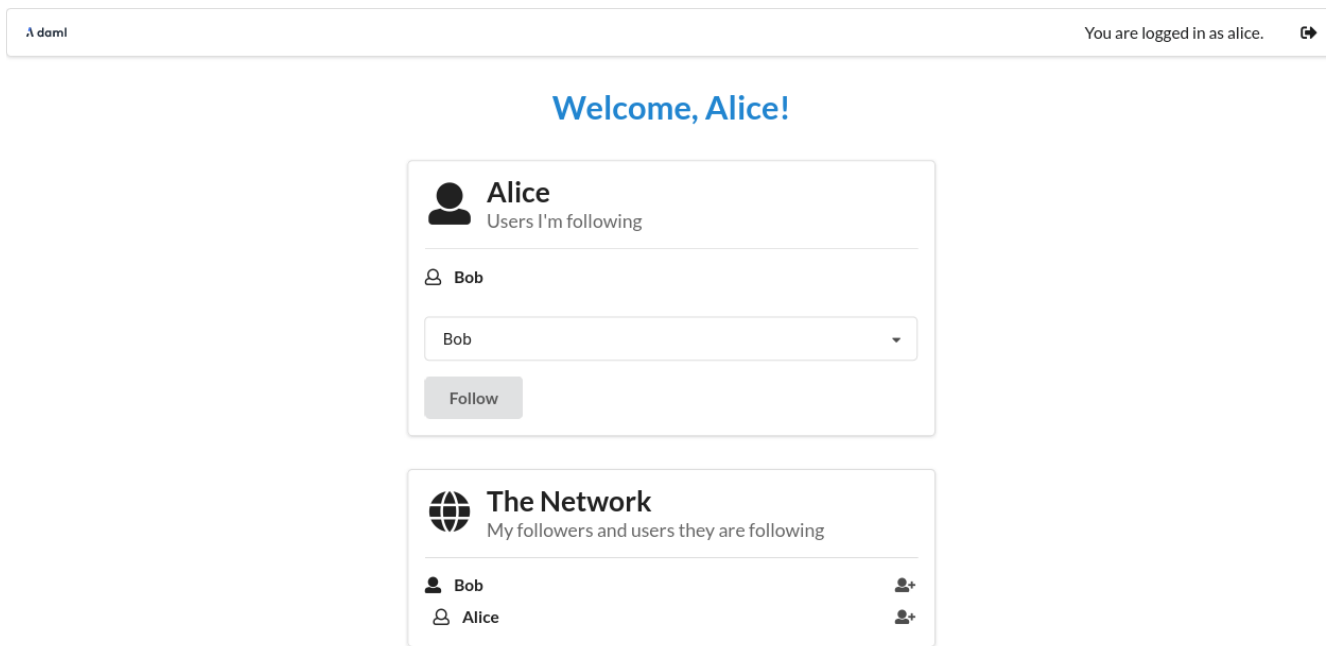

Then start another instance of the UI for Bob, running on port 3001 and connected to the HTTP JSON API on port 7576:

```
cd create-daml-app/ui
PORT=3001 REACT_APP_HTTP_JSON=http://localhost:7576 REACT_APP_LEDGER_ID=participant2 npm start
```

You can then log in with the user id `bob`.

Now that both parties have logged in, you can select Bob in the dropdown from Alice's view and follow him and the other way around.

After both parties have followed each other, the resulting view from Alice's side will look as follows.

Note that create-daml-app sets up human-readable aliases for party ids, which is why we can use those names to follow other parties instead of their party id.

23.5.3 What Next?

Now that you have started to become familiar with Daml and what a full Daml-based solution looks like, you can build your own first Daml application.

1. Use the [Daml language reference docs](#) to master Daml and build your own Daml model.
2. Test your model using [Daml scripts](#).
3. Create a simple UI following the example of the [Create Daml App](#) template used in this tutorial.
4. See how to compose [workflows across multiple Canton sync domains](#).
5. Showcase your application on [the forum](#).

Composability is currently an Early Access Feature in Alpha status.

Note: The example in this tutorial uses unsupported Scala bindings and codegen.

23.6 Composability

In this tutorial, you will learn how to build workflows that span several Canton sync domains. Composability turns those several Canton sync domains into one conceptual ledger at the application level.

The tutorial assumes the following prerequisites:

You have worked through the [Getting started](#) tutorial and know how to interact with the Canton console.

You know the Daml concepts that are covered in the [Daml introduction](#).

The running example uses the [ledger API](#), the Scala codegen (no longer supported by Daml) for Daml, and Canton's [identity management](#). If you want to understand the example code in full, please refer to the above documentation.

The tutorial consists of two parts:

1. The [first part](#) illustrates how to design a workflow that spans multiple sync domains.
2. The [second part](#) shows how to compose existing workflows on different sync domains into a single workflow and the benefits this brings.

The Daml models are shipped with the Canton release in the `daml/CantonExamples` folder in the modules `Iou` and `Paint`. The configuration and the steps are available in the `examples/05-composability` folder of the Canton release. To run the workflow, start Canton from the release's root folder as follows:

```
./bin/canton -c examples/05-composability/composability.conf
```

You can copy-paste the console commands from the tutorial in the given order into the Canton console to run them interactively. All console commands are also summarized in the bootstrap scripts `composability1.canton`, `composability-auto-transfer.canton`, and `composability2.canton`.

Note: Note that to use composability, we do have to turn off contract key uniqueness, as uniqueness cannot be provided across multiple sync domains. Therefore, composability is just a preview feature and explained here to demonstrate an early version of it that is not yet suitable for production use.

23.6.1 Part 1: A multi-synchronization-domain workflow

We consider the [paint agreement scenario](#) from the [Getting started](#) tutorial. The house owner and the painter want to enter a paint agreement that obliges the painter to paint the house owner's house. To enter such an agreement, the house owner proposes a paint offer to the painter and the painter accepts. Upon acceptance, the paint agreement shall be created atomically with changing the ownership of the money, which we represent by an IOU backed by the bank.

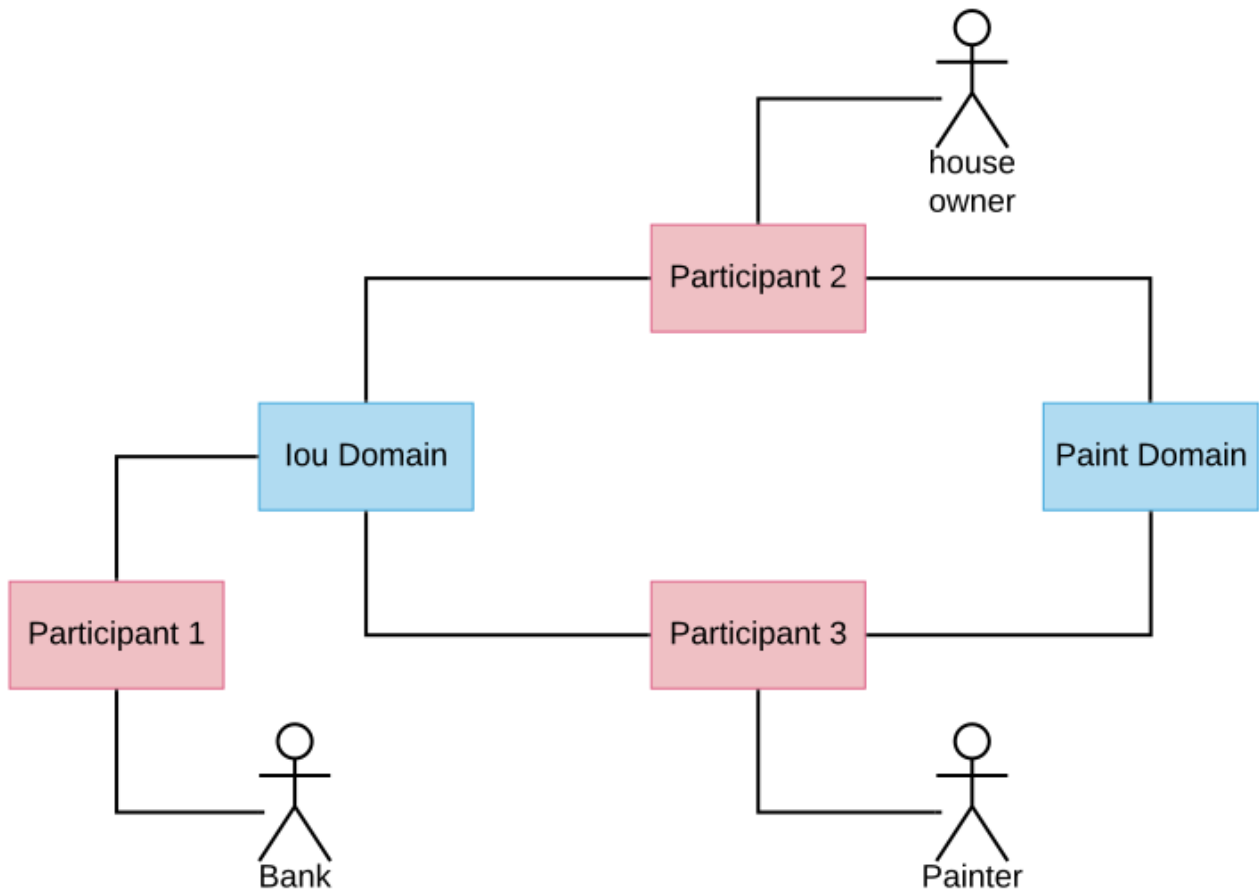

Atomicity guarantees that no party can scam the other: The painter enters the obligation of painting the house only if the house owner pays, and the house owner pays only if the painter enters the obligation. This avoids bad scenarios such as the following, which would have to be resolved out of band, e.g., using legal processes:

The house owner spends the IOU on something else and does not pay the painter, even though the painter has entered the obligation to paint the house. The painter then needs to convince the house owner to pay with another IOU or to revoke the paint agreement.

The house owner wires the money to the painter, but the painter refuses to enter the paint agreement. The house owner then begs the painter to return the money.

23.6.1.1 Setting up the topology

In this example, we assume a topology with two sync domains, `iou` and `paint`. The house owner's and the painter's participants are connected to both sync domains, as illustrated in the following diagram.

The configuration file `composability.conf` configures the two sync domains `iou` and `paint` and three participants.

```

canton {
  features {
    enable-preview-commands = yes
    enable-testing-commands = yes
  }
  monitoring {
    tracing.propagation = enabled
    logging.api.message-payloads = true
  }
  domains {
    iou {
      public-api.port = 13018
      admin-api.port = 13019
      storage.type = memory
      init.domain-parameters {
        unique-contract-keys = false
      }
    }
  }
}
  
```

(continues on next page)

(continued from previous page)

```

        protocol-version = 7
    }
}

paint {
    public-api.port = 13028
    admin-api.port = 13029
    storage.type = memory
    init.domain-parameters {
        unique-contract-keys = false
        protocol-version = 7
    }
}

participants {
    participant1 {
        ledger-api.port = 13011
        admin-api.port = 13012
        storage.type = memory
        init.parameters.unique-contract-keys = false
    }

    participant2 {
        ledger-api.port = 13021
        admin-api.port = 13022
        storage.type = memory
        init.parameters.unique-contract-keys = false
    }

    participant3 {
        ledger-api.port = 13031
        admin-api.port = 13032
        storage.type = memory
        init.parameters.unique-contract-keys = false
    }
}
}

```

As the first step, some sync domain parameters are changed (setting `transfer-exclusivity-timeout` will be explained in the [second part](#) of this tutorial). Then, all the nodes are started and the parties for the bank (hosted on Participant 1), the house owner (hosted on Participant 2), and the painter (hosted on Participant 3) are created. The details of the party onboarding are not relevant for show-casing cross-sync domain workflows.

```

// update parameters
iou.service.update_dynamic_domain_parameters(
    _.update(transferExclusivityTimeout = Duration.Zero)
) // disable automatic transfer-in

paint.service.update_dynamic_domain_parameters(
    _.update(transferExclusivityTimeout = 2.seconds)
)

// connect participants to the domain

```

(continues on next page)

(continued from previous page)

```

participant1.domains.connect_local(iou)
participant2.domains.connect_local(iou)
participant3.domains.connect_local(iou)
participant2.domains.connect_local(paint)
participant3.domains.connect_local(paint)

// the connect call will use the configured domain name as an alias. the
↳ configured
// name is the one used in the configuration file.
// in reality, all participants pick the alias names they want, which means that
// aliases are not unique, whereas a `DomainId` is. However, the
// alias is convenient, while the DomainId is a rather long string including a
↳ hash.
// therefore, for commands, we prefer to use a short alias instead.
val paintAlias = paint.name
val iouAlias = iou.name

// create the parties
val Bank = participant1.parties.enable("Bank")
val HouseOwner = participant2.parties.enable("House Owner")
val Painter = participant3.parties.enable("Painter")

// Wait until the party enabling has taken effect and has been observed at the
↳ participants
val partyAssignment = Set(Bank -> participant1, HouseOwner -> participant2,
↳ Painter -> participant3)
participant2.parties.await_topology_observed(partyAssignment)
participant3.parties.await_topology_observed(partyAssignment)

// upload the Daml model to all participants
val darPath = Option(System.getProperty("canton-examples.dar-path")).getOrElse(
↳ "dars/CantonExamples.dar")
participants.all.dars.upload(darPath)

```

23.6.1.2 Creating the IOU and the paint offer

To initialize the ledger, the Bank creates an IOU for the house owner and the house owner creates a paint offer for the painter. These steps are implemented below using the Scala bindings (no longer supported by Daml) generated from the Daml model. The generated Scala classes are distributed with the Canton release in the package `com.digitalasset.canton.examples`. The relevant classes are imported as follows:

```

import com.digitalasset.canton.BigDecimalImplicits._
import com.digitalasset.canton.examples.java.iou.{Amount, Iou}
import com.digitalasset.canton.examples.java.paint.{OfferToPaintHouseByOwner,
↳ PaintHouse}
import com.digitalasset.canton.participant.ledger.api.client.JavaDecodeUtil._
↳ decodeAllCreated
import com.digitalasset.canton.protocol.ContractIdSyntax._

import scala.jdk.CollectionConverters._

```

Bank creates an IOU of USD 100 for the house owner on the `iou` sync domain, by [submitting the command](#) through the ledger API command service of participant 1. The house owner then shares the IOU

contract with the painter such that the painter can effect the ownership change when they accept the offer. The share operation adds the painter as an observer on the IOU contract so that the painter can see the IOU contract. Both of these commands run over the `iou` sync domain because the Bank's participant 1 is only connected to the `iou` sync domain.

```
// Bank creates IOU for the house owner
val createIouCmd = new Iou(
  Bank.toProtoPrimitive,
  HouseOwner.toProtoPrimitive,
  new Amount(100.0.toBigDecimal, "USD"),
  List.empty.asJava
).create.commands.asScala.toSeq
val Seq(iouContractUnshared) = decodeAllCreated(Iou.COMPANION) (
  participant1.ledger_api.javaapi.commands.submit_flat(Seq(Bank), createIouCmd))

// Wait until the house owner sees the IOU in the active contract store
participant2.ledger_api.acs.await_active_contract(HouseOwner, iouContractUnshared.
  ↪id.toLf)

// The house owner adds the Painter as an observer on the IOU
val shareIouCmd = iouContractUnshared.id.exerciseShare(Painter.toProtoPrimitive).
  ↪commands.asScala.toSeq
val Seq(iouContract) = decodeAllCreated(Iou.COMPANION) (participant2.ledger_api.
  ↪javaapi.commands.submit_flat(Seq(HouseOwner), shareIouCmd))
```

Similarly, the house owner creates a paint offer on the `paint` sync domain via participant 2. In the `ledger_api.commands.submit_flat` command, we set the workflow id to the `paint` sync domain so that the participant submits the commands to this sync domain. If no sync domain was specified, the participant automatically determines a suitable sync domain. In this case, both sync domains are eligible because on each sync domain, every stakeholder (the house owner and the painter) is hosted on a connected participant.

```
// The house owner creates a paint offer using participant 2 and the Paint domain
val paintOfferCmd = new OfferToPaintHouseByOwner(
  HouseOwner.toProtoPrimitive,
  Painter.toProtoPrimitive,
  Bank.toProtoPrimitive,
  iouContract.id
).create.commands.asScala.toSeq
val Seq(paintOffer) = decodeAllCreated(OfferToPaintHouseByOwner.COMPANION) (
  participant2.ledger_api.javaapi.commands.submit_flat(Seq(HouseOwner),
  ↪paintOfferCmd, workflowId = paint.name))
```

23.6.1.3 Contracts and Their Synchronization Domains

In Canton, each contract is only known to the participants involved in that contract. The involved participants are the only ones with unencrypted copies of the contract, which they store in their respective private contract stores. No other participant has access to that data, even in encrypted form. The sync domain, in particular the sequencer that facilitates synchronization, will only store encrypted messages that only the receiving participant can decrypt.

In our terminology, the residence sync domain of a contract is the current agreement between the stakeholders of the contract where changes to the contract are to be communicated and where the sequence of actions on a contract is to be determined. A contract can reside on at most one sync

domain at any point in time. However, the contract is never stored by the sync domain in such a way that the sync domain learns about its existence or content.

23.6.1.4 Transferring a contract
